ANGINA

INDERAL® (PROPRANOLOL HCl) TODAY CAN TAKE THE CONCERN OUT OF TOMORROW.

Fewer angina attacks, less anginal pain, greater freedom from fear. That's what early use of INDERAL (propranolol HCl) can mean to today's angina patients. INDERAL works to reduce myocardial oxygen demand—by lowering the heart rate... reducing systolic blood pressure... decreasing contractility. Because it helps balance myocardial hemodynamics, INDERAL enables selected patients to do more—with less need for nitroglycerin, less fear of pain. When conventional measures are inadequate, prescribe INDERAL for angina early. INDERAL does more—so your patients may do more.

INDERAL®
(PROPRANOLOL HCl)
The sooner, the better.

Please see following page for Brief Summary of Prescribing Information.

P 24,135

INDERAL®
(PROPRANOLOL HCl)

THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

NEW TABLET SHAPE

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. In patients already receiving digitalis, propranolol may reduce the positive inotropic action of digitalis and may have an additive depressant effect on AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac failure has developed during propranolol therapy. At the first sign of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Give special consideration to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the heart to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery. In case of emergency surgery, the effects of propranolol can be reversed by administration of beta-receptor agonists such as isoproterenol or levarterenol, but such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), administer with caution, since propranolol may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta-receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS
—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-99). Also in unit dose package of 100 (NDC 0046-0421-91).
—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-99). Also in unit dose package of 100 (NDC 0046-0422-91).
—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-99). Also in unit dose package of 100 (NDC 0046-0424-91).
—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-99). Also in unit dose package of 100 (NDC 0046-0428-91).
The appearance of these tablets is a trademark of Ayerst Laboratories.
Store at room temperature (approximately 25° C).

INJECTABLE
—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).
Store at room temperature (approximately 25° C).

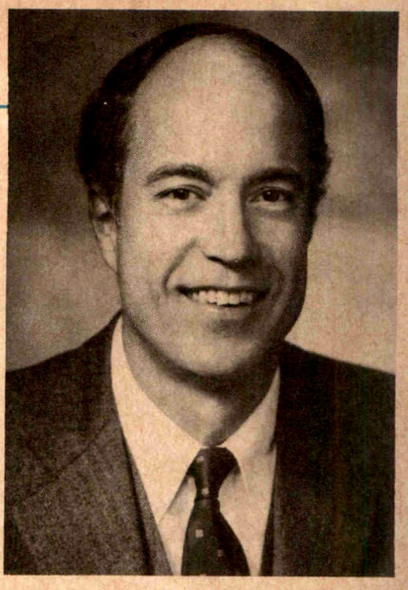
FROM THE EDITOR



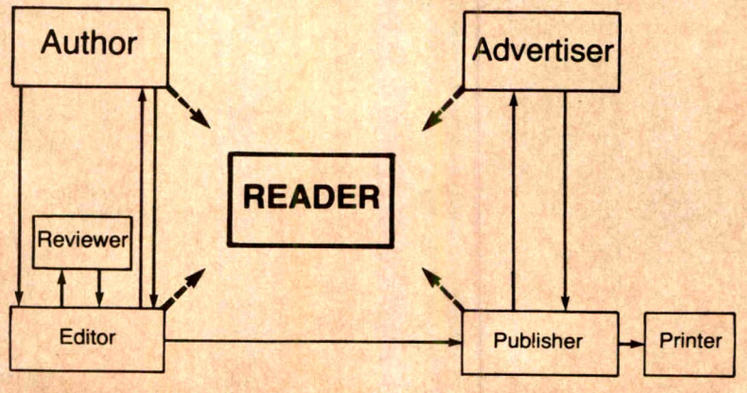
Author-Advertiser: Their Dependency on One Another

Occasionally I hear a physician complain about the number of advertising pages in medical journals. The number of medical journals, however, would be few and very expensive were it not for the ads. If there were no advertisements, a year's subscription to the AJC instantly would be approximately twice its present cost and later, as the number of subscribers diminished because of the journal's high price, even more. Although few physicians pick up a medical journal to read ads, there would be few journals to pick up were ads not present. Thus, physicians must appreciate the enormous contribution of advertisers to their education.

All elements of a medical journal (see figure) focus on providing the reader the best available information in the most presentable form. The 2 key elements in publishing medical articles are the authors (investigators) and advertisers. Among his many responsibilities, the publisher acquires the ads; the more ads acquired, the more text pages are provided. The publisher provides the editor with text pages based on several factors, a major one being the projected number of ads to be acquired over a specified period. During the first 6 months of 1983, each monthly issue of the AJC will average 228 text pages. Three additional issues, published during this period (in January, March, and May) will average 116 pages. All 9 issues consist of original articles; symposia sponsored by pharmaceutical companies are published separately and are not included in these figures. Thus, excluding symposia, 1,716 text pages will be published during the first 6 months of 1983. Without the advertisements, the number of text pages would diminish enormously and the patient would be the ultimate loser.

William C. Roberts

William C. Roberts, MD
Editor-in-Chief

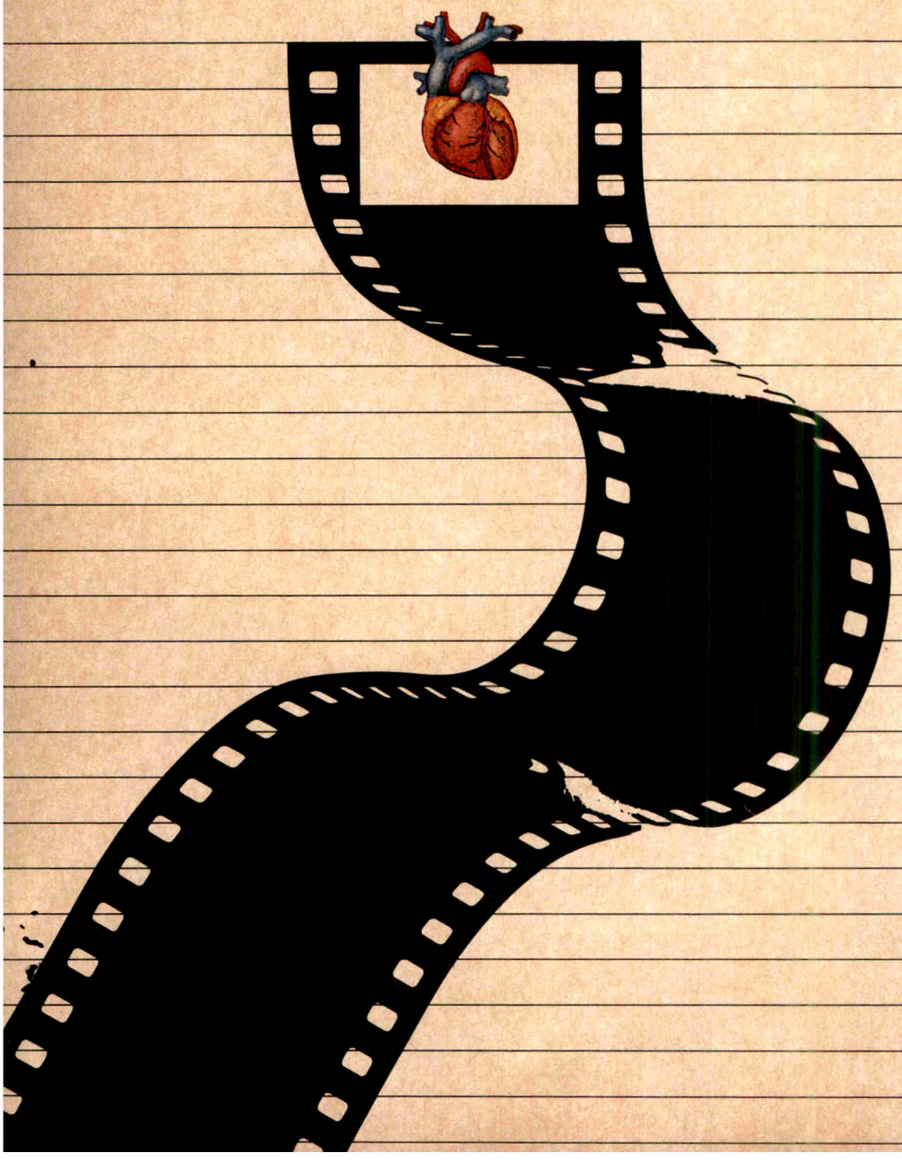


Smith Kline &French Laboratories
proudly invites you to the premiere of

PERFUSION & FUNCTION

a major motion picture exploring the most promising advances in cardiac imaging technology and the study of perfusion and myocardial function.

Thursday, March 24, 1983, at 1 p.m.
Pontchartrain Ballroom, Sections C and D
Sheraton, New Orleans
Buffet luncheon will be served. Seating will be limited to 300 people, on a first-come, first-served basis.



A panel of the investigators featured in the film will be available for questions and answers following the showing.

Participants in the film include:

Jay N. Cohn, M.D., F.A.C.C., Moderator
Robert J. Bache, M.D., F.A.C.C.
Harvey J. Berger, M.D.
Elias Botvinick, M.D.
Douglas P. Boyd, Ph.D.
B. Greg Brown, M.D., Ph.D.
Donald B. Doty, M.D.
Charles Higgins, M.D.
Joanne S. Ingwall, Ph.D.
Martin J. Lipton, M.D.
Melvin L. Marcus, M.D.
David Skorton, M.D.
Stephen F. Vatner, M.D.

As an organization accredited for continuing medical education, the University of Minnesota designates this presentation of "Perfusion & Function" as meeting the criteria for one credit hour in Category 1 of the Physician's Recognition Award of the American Medical Association/ACCME.

Xanax® 0.5 mg Tablets

alprazolam C IV

THE FIRST TRIAZOLO-BENZODIAZEPINE

Its triazolo ring gives XANAX a structure uniquely different from other benzodiazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

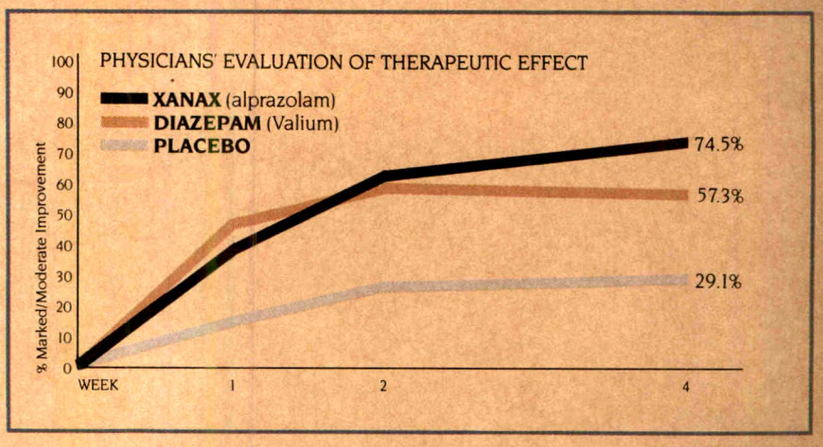
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient,* placebo-controlled, multicenter study.*

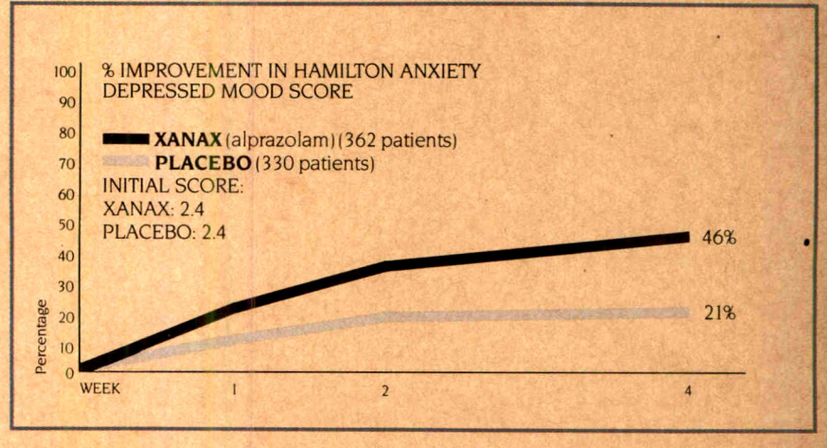


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam

XANAX® Tablets ℞
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about. (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. BS-1

*Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. *J Clin Psychiatry* 42 (9):347-351, 1981.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCC3

INSTRUCTIONS TO AUTHORS on page A28

INDEX TO ADVERTISERS on page A42

Indications: Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

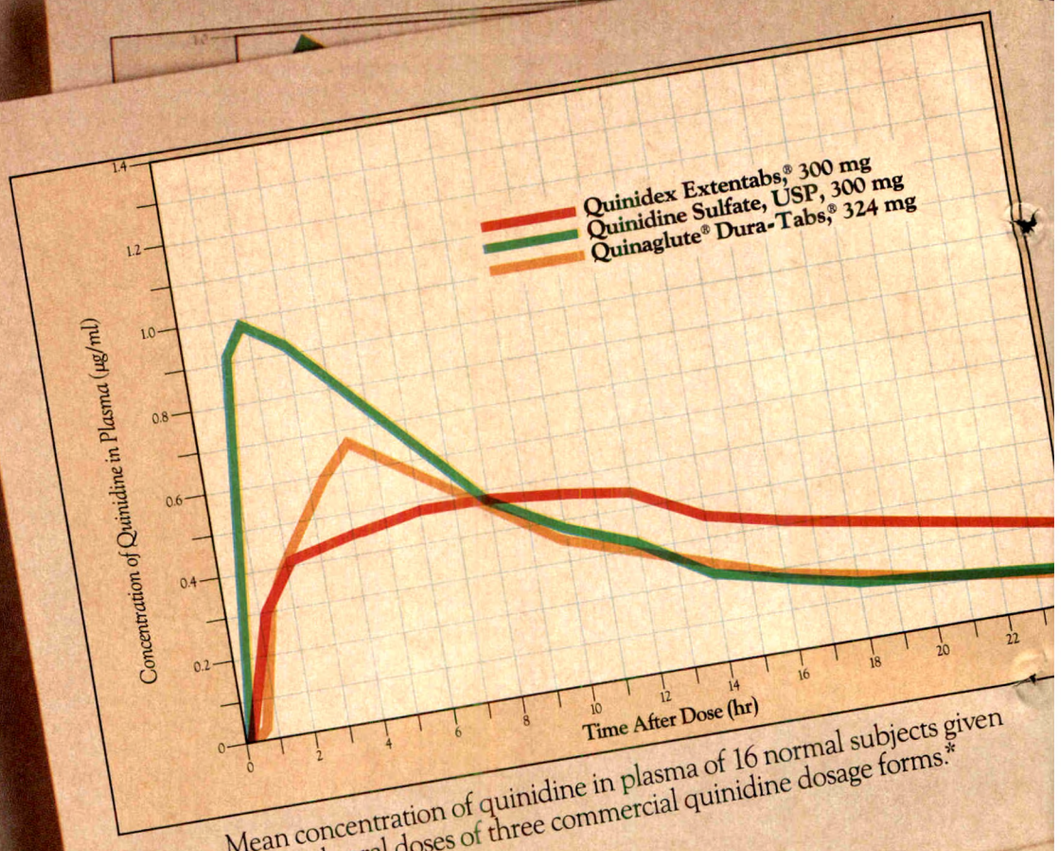
NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev. Dec. 1981



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex Extentabs® (Quinidine Sulfate, USP), 300 mg

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

For the proof, ask your Robins representative for a copy of the controlled crossover study. Or write S. Tisdale, M.D., 1211 Sherwood Avenue, Richmond, Va. 23220.

CONGESTIVE HEART FAILURE

919 Cleft Anterior Leaflet of the Mitral Valve With Intact Septa. A Study of 20 Cases

ELIO DI SEGNI and JESSE E. EDWARDS

Twenty pathologic specimens of heart, each with a cleft in the anterior leaflet of the mitral valve not associated with septal defects of persistent common atrioventricular canal (isolated cleft of the mitral valve), were studied. In 9 cases, there were either no associated anomalies or ones with no functional significance. In each of the other 11 cases, there were other significant cardiac anomalies associated, including ventricular septal defect and d-transposition of the great arteries. Functional consequences of the mitral anomaly were mitral insufficiency, subaortic stenosis, or the 2 together. Mitral insufficiency was related principally to the width of the cleft. Subaortic stenosis, when present, was due to the position of insertion of accessory chordae in the ventricular septum in a position under the commissure between the left and right aortic cusps or under the right aortic cusp.

927 Isolated Cleft Mitral Valve: A Variety of Congenital Mitral Regurgitation Identified by 2-Dimensional Echocardiography

ELIO DI SEGNI, JOHN L. BASS, RUSSELL V. LUCAS, and STANLEY EINZIG

Nine children aged 1 day to 12 years with cleft anterior mitral leaflet without atrial and/or ventricular septal defect of the endocardial cushion defect type were studied. One patient had 3 family members with an endocardial cushion defect. All 9 patients had an apical pansystolic murmur of mitral regurgitation (MR). The electrocardiogram showed a prolonged P-R interval in 3 patients; the QRS axis was normal in 5. Cardiac catheterization, performed in 4 patients disclosed increased pulmonary arterial wedge pressure in 2; no patient had significant subaortic stenosis. Cineangiographic left ventriculograms demonstrated severe MR in 3 patients but did not show a cleft mitral valve or goose-neck deformity in any patient. Surgical confirmation of the mitral cleft was obtained in 2 patients. Two dimensional echocardiography demonstrated the following features: The mitral anulus was normally positioned; the anterior mitral leaflet was divided by a cleft into 2 portions of different width in 5 patients and of equal width in 4; the edges of the cleft were thickened in 6 patients and of normal thickness in the 3 infants; accessory chordae tendineae extending from the basal portion of the anterior mitral leaflet to the ventricular septum were shown in 3 patients; mild narrowing of the left ventricular outflow tract was present in 3 patients; atrial and ventricular septa were intact in each patient; the mitral and tricuspid anuli were at different levels in each patient. Two-dimensional echocardiography is the only available method to reliably diagnose isolated cleft of the mitral valve clinically.

932 Pulmonary Atresia With and Without Ventricular Septal Defect: A Different Etiology and Pathogenesis for the Atresia in the 2 Types?

LYNN M. KUTSCHE and L. H. S. VAN MIEROP

Twenty-four hearts with pulmonary atresia or critical stenosis and intact ventricular septum were compared with 11 specimens of pulmonary atresia with ventricular septal defect, all from infants under 1 month of age. Distinct morphologic differences were found between the 2 groups. The pulmonary valve, although atretic, was usually well formed and the pulmonary trunk quite large in the former, whereas the valve was nearly always malformed, often reduced to a dimple, and the pulmonary trunk very small in the latter. In all cases with a small pulmonary trunk the ductus arteriosus was long, tortuous, and originated from the aortic arch in a proximal position, while in those with a normal or large pulmonary trunk the ductus usually had a normal shape. Based on these anatomic findings and present knowledge of cardiac embryology, the possible pathogenesis of these defects is discussed.

one-tablet-a-day dosage and... cardioselectivity*

ONE TABLET A DAY

TENORMIN®

(atenolol)

Tablets 50 mg

*Cardioselectivity denotes a relative preference for β_1 receptors, located chiefly in cardiac tissue. This preference is not absolute.

See last page of this advertisement for brief summary of prescribing information.

STUART PHARMACEUTICALS

TENORMIN® (atenolol)

A $beta_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a $beta_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m^2 (normal range is 100-150 ml/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m^2)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

936 Pulmonary Vein Wedge Angiography: Indications, Results, and Surgical Correlates in 25 Patients

ROBERT M. FREEDOM, GIACOMO PONGIGLIONE, WILLIAM G. WILLIAMS, GEORGE A. TRUSLER, C. A. FREDERICK MOES, and RICHARD D. ROWE

Pulmonary vein wedge angiography is a safe procedure that has been applied to 25 patients in our institute. It is designed (1) to demonstrate the presence or absence of mediastinal pulmonary arteries in patients with pulmonary atresia; (2) to determine the patency and calibre of a nonvisualized pulmonary artery when there is distal occlusion by either a shunt or pulmonary artery band; and (3) to determine the presence or absence of a mediastinal pulmonary artery in the patient with so-called isolated congenital unilateral absence of a pulmonary artery.

942 Familial Congenital Heart Disease: How Are the Various Types Related?

PIERRE CORONE, CATHERINE BONAITI, JOSUÉ FEINGOLD, SYLVIE FROMONT, and DOMINIQUE BERTHET-BONDET

The distribution of congenital heart lesions was studied in 238 families in which at least 2 members had congenital heart disease. Concordant lesions were found in 48% of the affected first-degree relatives and in 28% of the affected second- and third-degree relatives. The concordance rate was highly significant for all lesions studied in the first-degree relatives, with the exception of ventricular septal defect. Among the discordant pairs of lesions, some were significantly greater than the expected number (tetralogy of Fallot associated with ventricular septal defect, pulmonary stenosis, or transposition of the great arteries); others were significantly less frequent than would be expected on a random hypothesis (the association of ventricular septal defect with pulmonary stenosis). It is proposed that malformations which are anatomically dissimilar but resulting from the same heart segment disorder may have some common genes, and that interaction between genes may be responsible for "antagonism" between 2 defects. The embryologic segmental approach to congenital heart disease is reinforced by this genetic study.

946 Left Ventricular Wall Stress in Compensated Aortic Stenosis in Children

RICHARD DONNER, BLASE A. CARABELLO, IAIN BLACK, and JAMES F. SPANN

In order to explain the supernormal pump function usually observed in children with significant aortic stenosis (AS), parameters of left ventricular function were examined in 11 patients with AS and 10 normal children. In patients with AS, ejection fraction (0.88 ± 0.8) and mean velocity of circumferential fiber shortening (1.8 ± 0.35 circ/s) were greater than in normal subjects (0.64 ± 0.08, 1.22 ± 0.21 circ/s, respectively, $p < 0.001$). End-systolic volume index was less in patients with AS (9 ± 8 ml/m^2) than in normal subjects (27 ± 8 ml/m^2). In patients with AS, peak systolic wall stress (238 ± 51 dynes/cm^2·10^3) and end-systolic wall stress (24 ± 12 dynes/cm^2·10^3) were significantly less than in normal subjects (439 ± 85, 109 ± 30, respectively, $p < 0.001$). The ratio of end-systolic wall stress to end-systolic volume index, recently suggested as a measure of contractile function, was similar in patients with AS (3.3 ± 1.4) and normal subjects (4.3 ± 1.6). It appears that, in children with significant AS, the reduced end-systolic volume and abnormally low wall stress along with normal contractile function may explain the supernormal pump function.

952 Measurement of Systemic and Pulmonary Blood Flow and QP/QS Ratio Using Doppler and 2-Dimensional Echocardiography

STEPHEN P. SANDERS, SCOTT YEAGER, and ROBERTA G. WILLIAMS

A noninvasive method was developed for measuring systemic and pulmonary blood flow and flow ratios using 2-dimensional echocardiography and Doppler. This method compared favorably with the Fick method for estimating blood flow and Qp/Qs ratios. Outflow tract stenosis, semilunar regurgitation, and patent ductus arteriosus were the only limitations to the use of this method encountered thus far. The authors anticipate that this technique will be useful in evaluation and follow-up of pediatric and adult patients.

VALVULAR HEART DISEASE

957 Long-Term Failure Rate and Morphologic Correlations in Porcine Bioprosthetic Heart Valves

FREDERICK J. SCHOEN, JOHN J. COLLINS, and LAWRENCE H. COHN

Of 1,110 porcine bioprosthetic heart valves implanted between 1972 and 1982, 23 have had documented primary tissue dysfunction, at an average postoperative interval of 55 months. The frequency of dysfunction was 6.8% (11 of 161) for mitral and 4.1% (7 of 172) for aortic valves implanted for ≥5 years. Valves implanted for

Continued on Page A16

<5 years had a failure rate of only 0.7%. Actuarially calculated freedom from pr
7% for the mitral valve and 91 ± 4% for the aortic valve at 10 years. The most f
recovered bioprostheses was cuspal tearing associated with calcific deposits (7
plantation 66 months), but cuspal tears in the absence of calcification occurred in
months).

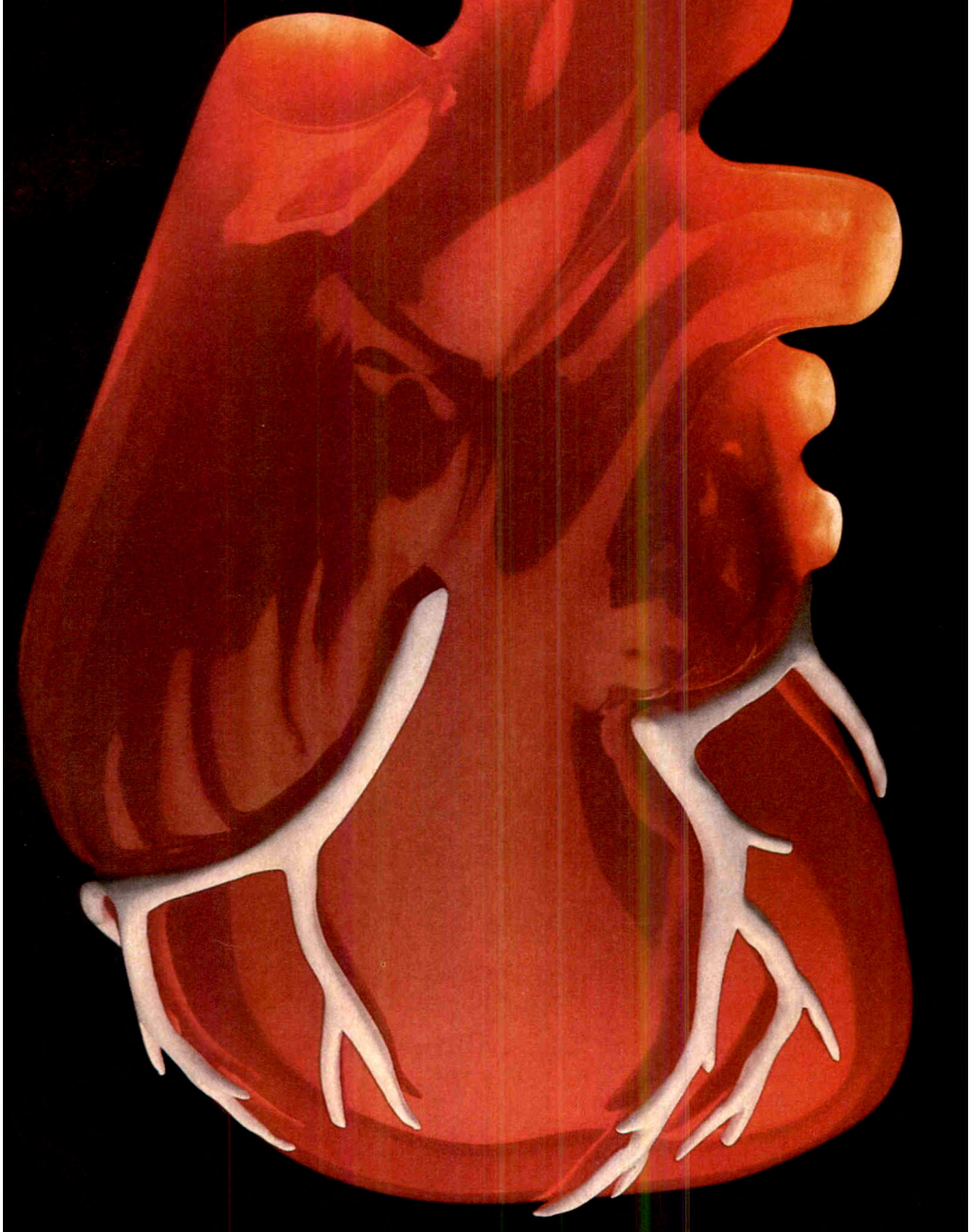
Announcing a major advance
in cardiovascular therapy

New CARDIZEM™ (diltiazem HCl)

CALCIUM CHANNEL BLOCKADE
from Marion Laboratories



Potent coronary vasodilation with a
distinctive hemodynamic profile

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

© 1983, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries!

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function[3]

While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.

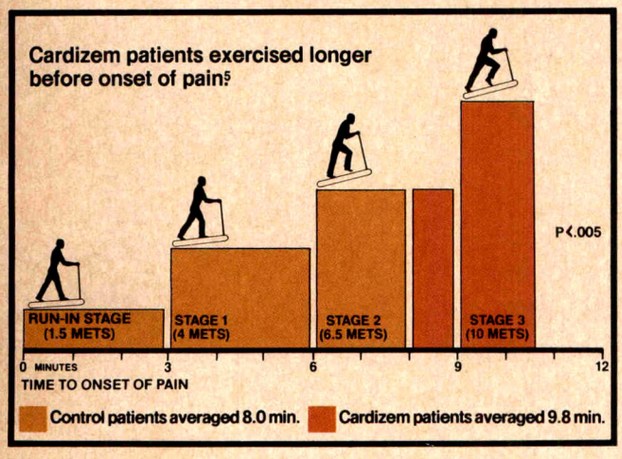
CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

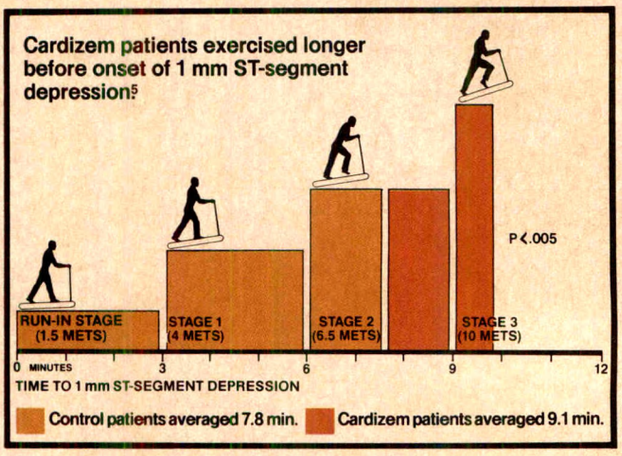
Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

Please see full prescribing information on last page of this ad.

EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:
A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

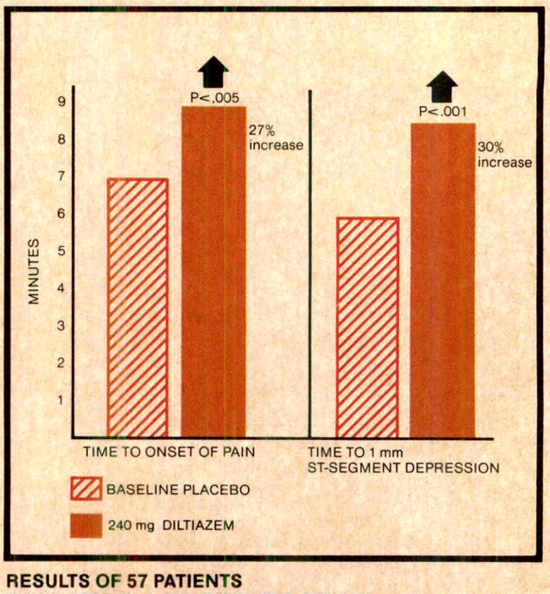
The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

5. Pool PE, Seagren SC, Bonanno JA, et al: The treatment of exercise-inducible chronic stable angina with diltiazem: Effect on treadmill exercise. *Chest* 78(July suppl): 234-238, 1980.
6. Hossack KF, Pool PE, Steele P, et al: Efficacy of diltiazem in angina on effort: A multicenter trial. *Am J Cardiol* 49:567-572, 1982.

*This study is a report from one center in a multicenter study.

CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

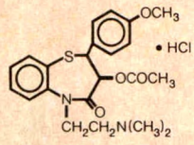
In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

986 Detection and Estimation of Rheumatic Mitral Regurgitation in the Presence of Mitral Stenosis by Pulsed Doppler Echocardiography

ASHVIN K. PATEL, GEORGE G. ROWE, JAMES H. THOMSEN, SHIRAZ P. DHANANI, PETER KOSOLCHAROEN, and LOU ELLEN W. LYLE

The sensitivity and specificity of pulsed Doppler echocardiography in diagnosing and estimating the severity of mitral regurgitation (MR) in the presence of rheumatic mitral stenosis was studied in 34 patients. When patients were classified for mild, moderate, and severe MR, the sensitivity of pulsed Doppler echocardiography for diagnosis was 54, 88, and 100%, respectively; overall accuracy was 79% and specificity 100%. Based on average systolic dispersion on a time-interval histogram, groups of patients with mild MR could be differentiated from those with moderate ($p < 0.05$) and severe ($p < 0.01$) MR; significant overlap of individual values occurred, however. In 7 of 11 patients with moderate to severe MR, systolic turbulence also was detected in the left atrium. Pulsed Doppler echocardiography was sensitive and specific in diagnosing moderate to severe MR in the presence of mitral stenosis. Assessment of the precise severity of MR is still a problem in individual patients.

992 Clinical and Echocardiographic Features of Patients With Mitral Anular Calcification: Comparison With Age- and Sex-Matched Subjects

CHANDRA K. NAIR, WILBERT S. ARONOW, MICHAEL H. SKETCH, SYED M. MOHIUDDIN, TOM PAGANO, DENNIS J. ESTERBROOKS, and TOM T. HEE

Clinical and echocardiographic features of 104 patients (53 women and 51 men) with mitral anular calcification (MAC) were compared with those of 121 age- and sex-matched controls (62 women and 59 men) without MAC. The incidence of coronary artery disease, rheumatic heart disease, systemic hypertension, and diabetes mellitus was similar in the 2 groups. Patients with MAC had a greater incidence of cardiomegaly ($p < 0.001$), cardiac conduction defects ($p < 0.001$), and aortic outflow tract murmurs ($p < 0.005$) than control patients. Patients with MAC and without aortic root calcification had a higher incidence ($p < 0.001$) of conduction defects than patients with aortic root calcification who did not have MAC. Control patients with and without aortic root calcification had a similar incidence of conduction defects. A higher incidence of atrioventricular block ($p < 0.025$) and of bundle branch block, left anterior hemiblock, or intraventricular conduction defect ($p < 0.05$) was present in patients with anterior MAC than in those with posterior MAC. In conclusion, patients with MAC have a higher incidence of cardiomegaly, cardiac conduction defects, and aortic outflow tract murmurs than a control group.

996 Prosthetic Mitral Valve Motion During Cardiac Dysrhythmias: An Echocardiographic Study

IOANNIS P. PANIDIS, JOEL MORGANROTH, DANIEL DAVID, CHIN C. CHEN, and MORRIS N. KOTLER

M-mode echocardiography was performed in 36 patients with normally functioning prosthetic mitral valves (Björk-Shiley, Starr-Edwards, and Beall valve) during various rhythm and conduction disturbances. Premature closure of the prosthetic mitral valve in diastole with a "sharp" closing motion was observed during first-degree atrioventricular block, atrial fibrillation with ventricular rates <60 beats/min, and atrial flutter. A "rounded" premature valve closure in diastole was seen during atrial tachycardia and complete heart block. These findings explain some of the mechanisms of mitral valve motion and should be considered in the echocardiographic evaluation of suspected malfunctioning prosthetic mitral valves.

VALVULAR HEART DISEASE: REVIEW

1005 Morphologic Features of the Normal and Abnormal Mitral Valve

WILLIAM C. ROBERTS

Certain anatomic and functional features of the normal and abnormal mitral valve are reviewed. Of 1,010 personally studied necropsy patients with severe cardiac dysfunction from primary valvular heart disease, 434 (43%) had mitral stenosis (MS) with or without mitral regurgitation (MR) (the etiology was rheumatic in all), and 165 (16%) had pure MR (papillary muscle dysfunction excluded). Pure MR when associated with dysfunction of the aortic valve (68 patients) was usually rheumatic in etiology, but when unassociated with aortic valve dysfunction was usually nonrheumatic in origin. Review of operatively excised mitral valves in patients with pure MR unassociated with aortic valve dysfunction and excluding papillary muscle dysfunction disclosed mitral valve prolapse to be the cause of MR in 60 (88%) patients, infective endocarditis to be the cause in 5, and a rheumatic origin in only 3. All 68 patients were >30 years of age.

1029 Improved Cross-Sectional Echocardiographic Technique for Visualization of the Retrocardiac Descending Aorta in the Long-Axis View: Normal Findings and Abnormalities in Saccular and/or Dissecting Aneurysms

PATRICIA C. COME

An improved ultrasonic technique for visualization of the retrocardiac descending aorta is described. Excellent delineation of the aortic walls was obtained in 92% of 50 consecutive patients. Five patients with saccular and dissecting aneurysms involving the retrocardiac aorta were also examined, and abnormalities were essentially identical to those seen with computed tomography and aortography. Intimal flaps were visualized by ultrasound in all 5 patients and were seen to oscillate reproducibly with the cardiac cycle, suggesting differential rates of filling of false and true lumens.

1033 Respiratory Effects on Systolic Time Intervals During Pericardial Effusion

DAVID H. SPODICK, DELORES PALADINO, and ATHAN P. FLESSAS

Fourteen patients with pericardial effusion and no sign of hemodynamic embarrassment (specifically no pulsus paradoxus or other cardiocirculatory abnormality) had exaggerated changes in systolic time intervals during respiration compared with normal subjects and with 5 concurrent control patients with noneffusive ("dry") pericarditis. Excessive pericardial fluid may not cause clinical manifestations but is not physiologically inert.

1036 Usefulness of the Echocardiographic Right Ventricular Measurements in Estimating Right Ventricular Hypertrophy and Right Ventricular Systolic Pressure

RAVI PRAKASH and HARUO MATSUKUBO

Right ventricular wall thickness measurements were made in 111 patients by echocardiography. Anatomic and echocardiographic findings were compared in 36 subjects: right ventricular wall thickness had a sensitivity of 90% and a specificity of 94% in the diagnosis of right ventricular hypertrophy. Echocardiographic and hemodynamic findings were compared in the remaining 75 patients. The right ventricular wall thickness and right ventricular systolic pressure had a linear correlation, and estimates of right ventricular systolic pressure were fairly good ($r = 0.83$). It is concluded that echocardiographic measurements of right ventricular wall thickness are useful in estimating right ventricular systolic pressure and right ventricular hypertrophy.

OUR HANDS-ON

Microprobe.™

Go ahead, put your hand right over this photograph. It's actual size and it will give you a good idea of just how small our Microprobe™ really is. It's the smallest mechanical sector probe in Ultrasound. And you know the inherent imaging benefits of that.

Like a phased array probe, Microprobe™ provides small size and manuever-ability when performing difficult ultrasound studies. And like the best conventional mechanical sector probes, Microprobe™ provides superior image quality.

But don't take our word for it, stop by our booth at ACC for a real hands-on demonstration.

(Actual Size)

E K O L I N E

In diagnostic ultrasound, Microprobe™ is a trademark belonging only to EkoLine.

ACC Booth Number 1149, Rivergate.

DEMONSTRATION

Video Page Printer.

You really have to hand it to our new Video Page Printer. It provides an inexpensive alternative for producing hard copy Sector and M-mode records. Less than a nickel a copy — the least expensive alternative is more than five times that much. And our Video Page Printer's purchase price is one-third the cost of a stand-alone strip chart recorder. If you do as many as 100 studies a month, the Video Page Printer virtually pays for itself in one year's hard copy savings. But what about image quality? You'll just have to see for yourself. Stop by our booth at ACC and ask for a test drive. We think you'll agree that our new Video Page Printer wins hands down for economy and image quality.

INSTRUCTIONS TO AUTHORS

Manuscripts are received with the understanding that they are submitted solely to THE AMERICAN JOURNAL OF CARDIOLOGY and they become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

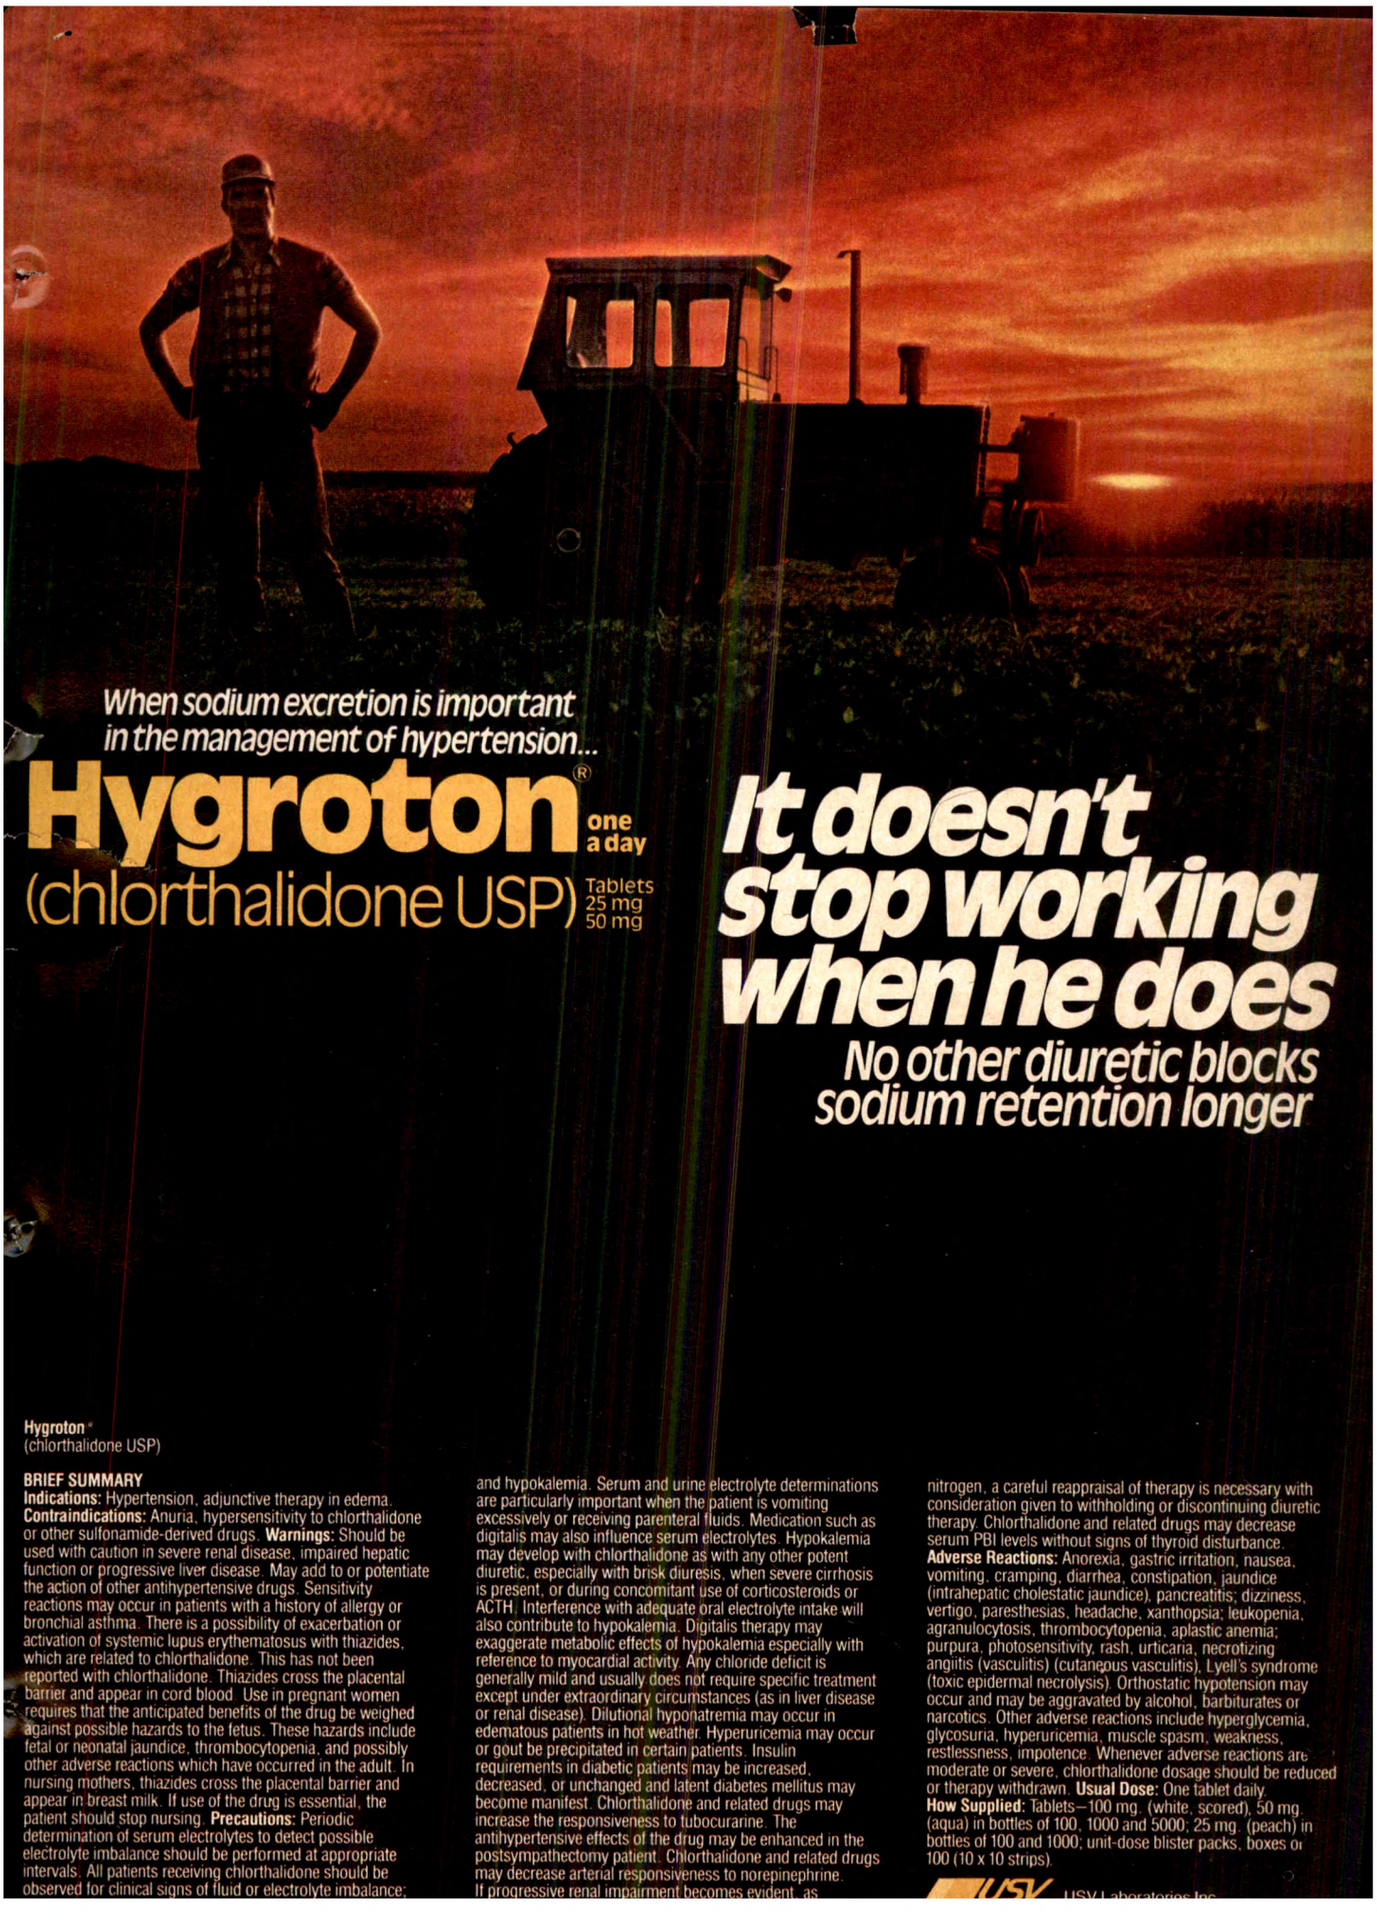
FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating data on patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present; a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.



When sodium excretion is important in the management of hypertension...

Hygroton®

one a day

(chlorthalidone USP) Tablets 25 mg 50 mg

It doesn't stop working when he does

No other diuretic blocks sodium retention longer

Hygroton®
(chlorthalidone USP)

BRIEF SUMMARY
Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

CONGENITAL HEART DISEASE

Cleft Anterior Leaflet of the Mitral Valve With Intact Septa

A Study of 20 Cases

ELIO DI SEGNI, MD and JESSE E. EDWARDS, MD

Twenty pathologic specimens of heart, each with a cleft in the anterior leaflet of the mitral valve not associated with septal defects of persistent common atrioventricular canal (isolated cleft of the mitral valve), were studied. In 9 cases, there were either no associated anomalies or ones not of functional significance. In each of the other 11 cases there were other significant associated cardiac anomalies, including ventricular septal defect and d-transposition of the great arteries. Functional consequences of the mitral anomaly were mitral insufficiency, subaortic stenosis, or both. Mitral insufficiency was related principally to the width of the cleft. Subaortic stenosis, when present, was due to the position of insertion of accessory chordae in the ventricular septum in a position under the commissure, between the left and right aortic cusps or under the right aortic cusp.

Cleft anterior leaflet of the mitral valve, when not associated with septal defect of persistent common atrioventricular canal (so-called endocardial cushion defect) is rare. Twenty such cases observed in autopsy-derived specimens are described. A review of this material seems appropriate in that the condition is not well known, and only a few reports have dealt with its clinical and pathologic features[1–21]; the clinical recognition of this anomaly is now potentially possible with characteristics of 2-dimensional echocardiography.[21,22]

Methods

Twenty specimens of heart with a cleft in the center of the anterior mitral leaflet were available for restudy. There was an equal distribution among males and females. Down's syndrome was present in 4 cases. The ages ranged from stillborn to 74 years. The mean age at death was about 4 years. Situs solitus was present in each subject.

The specimens were derived from numerous sources over a period exceeding 22 years. The clinical data supplied to us varied. To some extent this was related to the time when any given specimen was received. Therefore, interpretation of functional consequences of the anomaly, whether mitral insufficiency, subaortic stenosis, or both were present or absent, was judged primarily from the details observed in the pathologic specimens.

Our evaluation of the anatomy of the mitral valve included measurements of the dimensions of the mitral valve and of the cleft as shown in Figure 1. Certain terms were derived from these measurements: (1) width of cleft, (2) depth of cleft, (3) width of base of anterior leaflet, and (4) depth of anterior leaflet. Certain ratios were derived from these absolute measurements.

The presence and the insertion of ectopic chordae were recorded. The position of ventricular insertion of such chordae was related to the specific overlying aortic cusps, as shown in Figure 2.

Results

The 20 cases could be classified into 2 groups as defined later (Table I). Group I consisted of 9 cases in which the cleft of the anterior mitral leaflet was asso-

ciated either with no anomalies or anomalies of minor significance. In Group I, additional anomalies were present in 4 cases. These were fossa ovalis type (secundum) atrial septal defect in 2 cases, and small left ventricular-right atrial communication and floppy tricuspid valve in 1 case each. In each of the 11 cases in Group II, a cleft in the anterior mitral leaflet was associated with other cardiac anomalies, each of significant nature. These cases were further subdivided according to whether transposition was absent or present. Thus, in our cases transposition was absent (Group IIA). Some form of transposition was present in 7 cases (6 with d-transposition, Group IIB) and 1 with classical corrected transposition (l-transposition, Group IIC). In the latter case, the cleft was in the right-sided mitral valve.

Anatomic Features of the Mitral Valve

In the normal case, the width of the base of the anterior leaflet is less than that of the posterior leaflet by a ratio of about 1:2.[23] In 13 of our 20 cases this ratio was different, the width of the anterior leaflet at its base being equal to or greater than the corresponding part of the posterior leaflet. This discrepancy from the usual was about equally distributed among cases of Groups I and II.

The leaflets of the mitral valve and the papillary muscles were normally oriented in 8 cases and rotated clockwise in 12 cases. This rotation appeared to have resulted from the abnormally posterior position of the anterolateral papillary muscle. This phenomenon was seen in 12 cases (4 of Group I, 3 of Group IIA, and 5 of Group IIB).

The cleft of the anterior mitral leaflet was usually shaped like an inverted V, with the apex pointing toward the valve ring. In 2 cases the cleft had a rectangular shape. The cleft extended for from 30 to 90% of the distance between the free margin and the base of the anterior mitral leaflet. The anterior leaflet was divided into halves except at its base, where the halves of the cleft leaflet were continuous. In 8 specimens, the cleft was located exactly in the center of the anterior mitral leaflet (Fig. 3). In the remaining cases, the cleft was

eccentric. In 5 cases (4 of Group I) the anterior portion of the cleft leaflet was wider than the posterior. The posterior portion of the anterior leaflet was wider than the anterior in 7 cases, 4 being among the cases with d-transposition of the great arteries (Fig. 4).

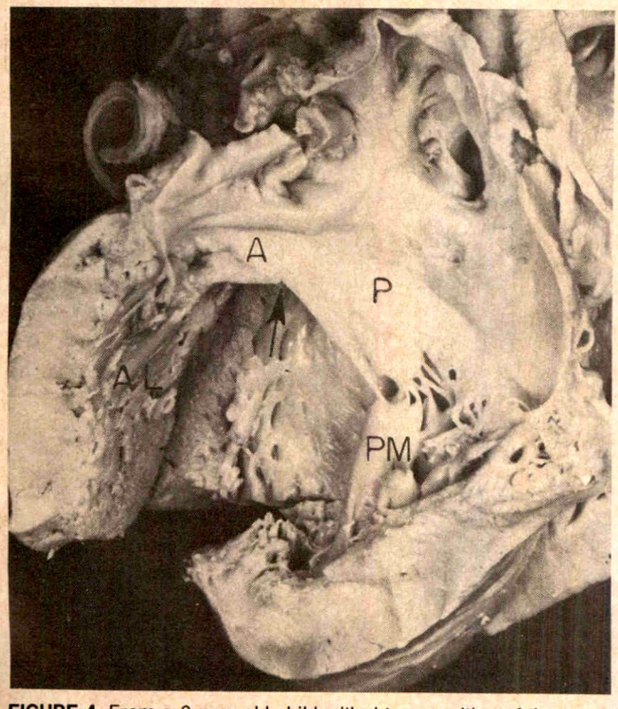

FIGURE 4. From a 2-year-old child with d-transposition of the great arteries. The atrial aspect of the cleft anterior mitral leaflet is shown. The posterior portion of the leaflet is wider than the anterior. The edges of the cleft are thin. Abbreviations as in Figure 3.

The edges of the cleft were thin and smooth in 8 specimens (Fig. 3 and 4). In the other 12 cases, the edges of the defect were thickened by nodular fibrous tissue, while elsewhere the leaflet remained thin (Fig. 5 to 7). The thickness of the edges was 2 to 4 mm in these cases. A clear positive relation existed between the ages of the subjects and the thickness of the edges of the cleft.

Normal chordae tendineae extended from the anterior portion of the anterior leaflet to the anterolateral papillary muscle and from the posterior portion of the anterior leaflet to the posteromedial papillary muscle. Accessory chordae tendineae or a raphe-like fibrous structure constantly extended from the anterior mitral leaflet to the septal or anterior walls of the left ventricle. The valvular origin of the accessory chordal tissue was into that part of the anterior leaflet that lay between the apex of the cleft and the basal attachment of the leaflet (Fig. 3 right, 5 bottom, 6 right, and 7). In only 2 cases were accessory chordae attached to the edges of the cleft (Fig. 7).

The insertion of these structures was to the ventricular septum in 16 cases (Fig. 3 right, 5 bottom, 6 right, and 7) and to the anterior wall of the left ventricle in 4 cases, each with d-transposition.

When insertion occurred to the ventricular septum it was to the membranous septum or the crest or body of the muscular septum. The sites of ventricular insertion with respect to the position of the above-lying aortic sinuses were as follows (Fig. 8): (1) insertion of accessory tissue under the commissure between the left and right aortic cusps (position 1), 3 cases; (2) under the right aortic cusp (position 2), 6 cases; (3) under the commissure between the right and posterior aortic cusps (position 3), 5 cases; (4) under the noncoronary aortic cusp (position 4), 1 case; (5) under the left aortic cusp (position 6), 4 cases.

As will be shown later, the insertion site of the chordal or raphe-like accessory tissue was a determining factor as to whether or not left ventricular outflow tract obstruction was considered present.

Associated Anomalies

In some of the cases, anomalies in addition to a cleft mitral valve were present. These are divided into 2 groups: anomalies that are either part of or frequently associated with the endocardial cushion defect, and those that appear unrelated to the endocardial cushion defect.

Anomalies related to the endocardial cushion defect: *Mitral valve:* A double mitral orifice was found in 2 cases.

Left ventricle: The ratio between the length of the outflow tract and the inflow tract of the left ventricle was as in normal hearts in 8 cases. In 12 cases, this ratio was similar to what is found in typical atrioventricular canal defects in which the inflow dimension of the left ventricle is distinctly shorter than the outflow dimension.[24]

Ventricular septum: The summit of the ventricular septum was deficient in 4 hearts, each in Group I. The muscular septum in these cases resembled the "scooped out" aspect seen in classic endocardial cushion defect (Fig. 7). This deficiency was closed by a membrane which we considered to be tricuspid tissue closing a ventricular septal defect.

Tricuspid valve: A cleft in the septal leaflet of the tricuspid valve was present in 4 hearts.

Anomalies not related to the endocardial cushion defect: Anomalies that are not considered part of the endocardial cushion defect were found in 12 of the 13

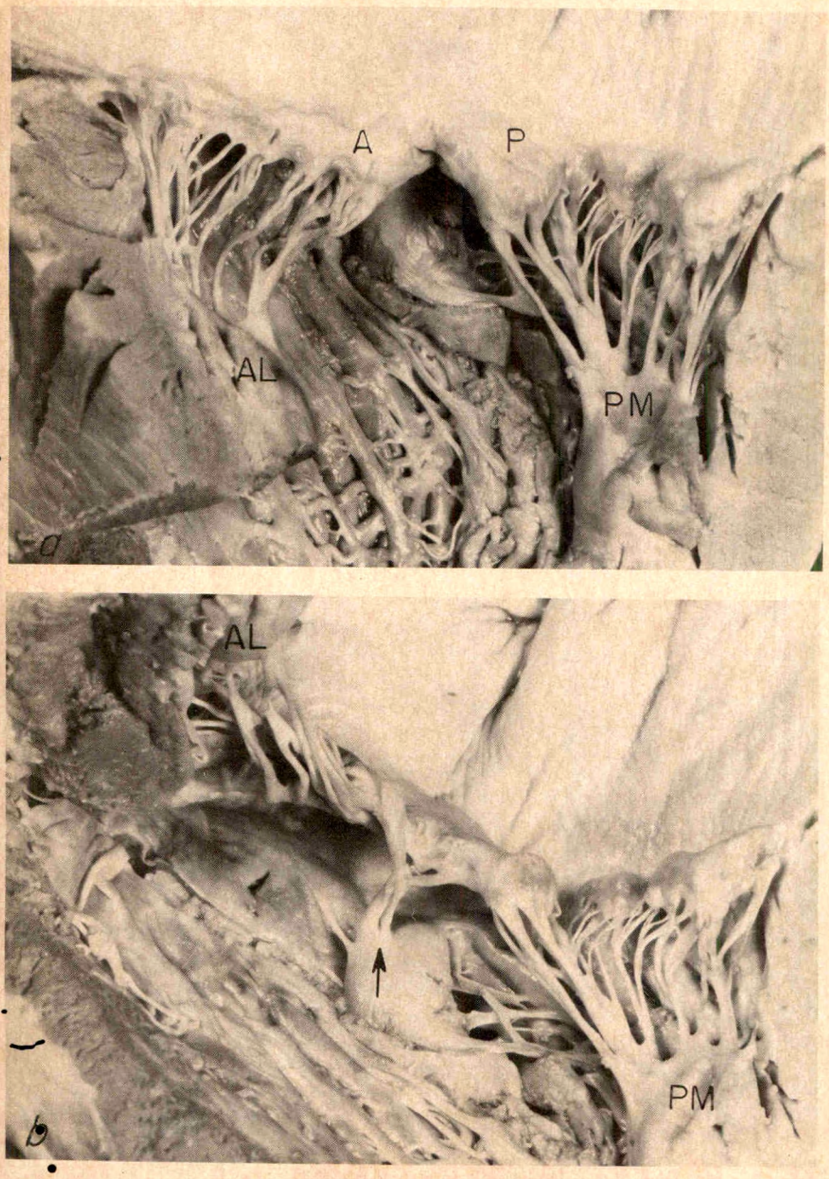

FIGURE 5. Cleft mitral valve from a 74-year-old in whom a mild prolapse of the tricuspid valve was also present. **a,** opened mitral valve viewed from the atrial aspect. The edges of the cleft are thickened by fibrous tissue, **b,** mitral valve viewed from its free edge. specimens without transposition and are listed in Table I. Of the 2 hearts with large ventricular septal defects, in each the defect was not of the so-called atrioventricular canal type. In the first of the 2, the defect was located in the area of the membranous septum. In the second case, the defect was located in the muscular septum. In the latter case, coarctation of the aorta, bicuspid aortic valve, and patent ductus arteriosus were

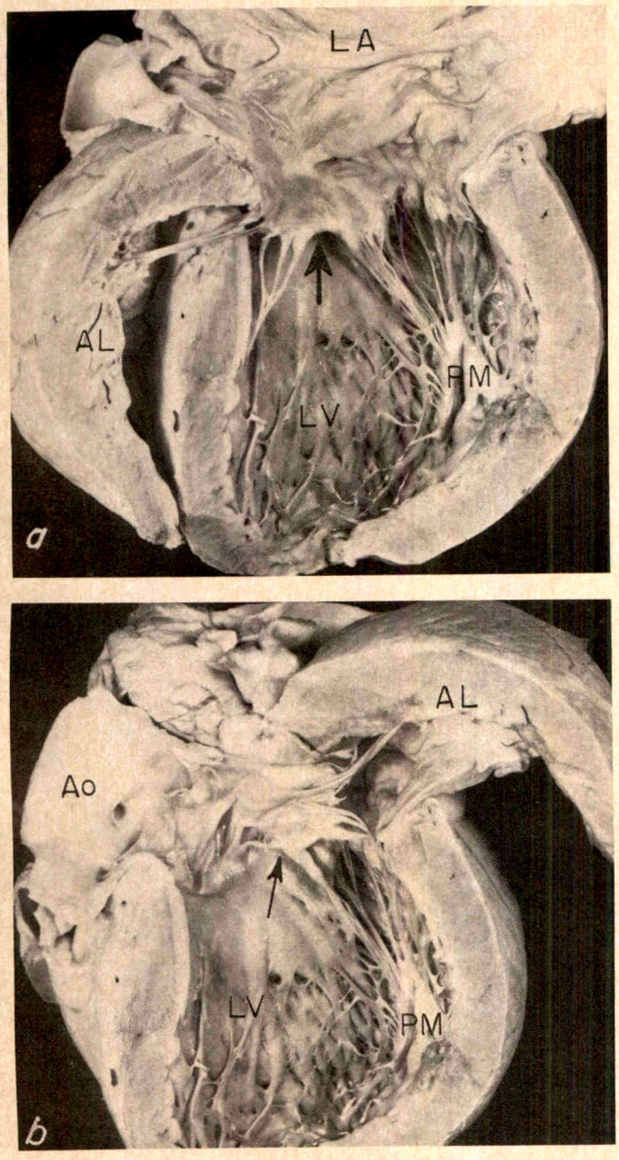

FIGURE 6. Cleft mitral valve in a 3-year-old boy with severe mitral insufficiency. **a,** atrial aspect of opened mitral valve. A shallow cleft (**arrow**) with thickened margins is present in the center of the anterior leaflet. **b,** ventricular aspect of anterior mitral leaflet from interior of left ventricle. An accessory chorda tendinea (**arrow**) and, above that, a raphe-like ridge extend from the mitral valve to the membranous septum in a position below the commissure between the right and posterior aortic cusps (position 3). In this case severe mitral insufficiency was present. This was apparently due to the restriction of the motion of the anterior mitral leaflet caused by the abnormal accessory chordae rather than to the extent of the cleft. LA = left atrium; other abbreviations as in Figure 3.

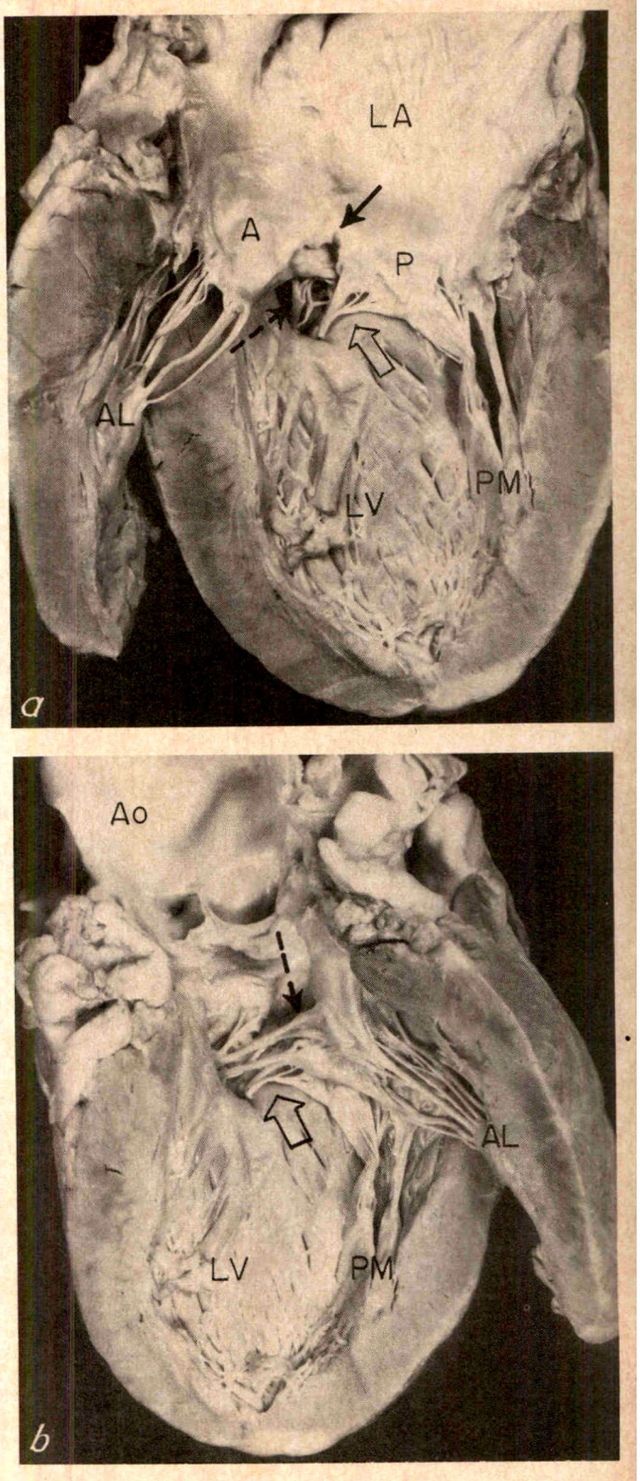

FIGURE 7. Cleft mitral valve in a 41-year-old man with Down's syndrome. **a,** opened mitral valve from its atrial aspect is shown. **a,** the ventricular aspect of the mitral valve is shown. **Solid arrow** in **a** points to the apex of the cleft. Accessory chordae extend from the anterior margin (**broken arrow**) and from the posterior margin (**open arrow**) of the cleft to the margins of the deficient ventricular septum. The "scooped out" appearance of the muscular septum is similar to that seen in classic endocardial cushion defect. The summit of the ventricular septum is closed by a membrane which was judged to be tissue of the tricuspid valve. LA = left atrium; other abbreviations as in Figure 3.

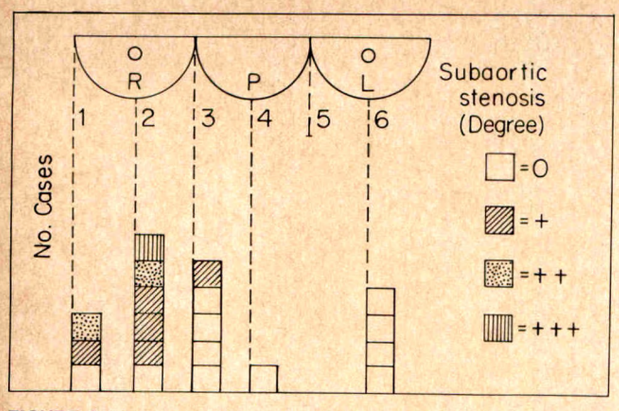

FIGURE 8. Various positions of ectopic chordal insertion as defined in Figure 2, according to the degree of subaortic stenosis. 0 = no subaortic stenosis; + = mild, ++ = moderate, and +++ = severe subaortic stenosis, respectively. The case with l-transposition of the great arteries is not included.

also present. In the 1 case with aortic atresia, septal attachment of accessory chordae of the cleft mitral valve caused subaortic obstruction, in addition.

Functional Consequences

As stated, the principal basis for interpreting functional effects of the anomaly of the mitral valve was the appearance of the specimen. The 2 major consequences of the cleft in the anterior mitral valve appeared to be mitral insufficiency and subaortic stenosis. The principal factors favoring an opinion that mitral insufficiency had been present were left atrial enlargement, right ventricular hypertrophy, and, to some extent, left ventricular enlargement.

Subaortic stenosis was judged to have been present when associated anomalous attachment of the anterior leaflet of the mitral valve to either the ventricular septum or anterior wall of the right ventricle had restricted significant movement of the anterior mitral leaflet from the septal wall of the left ventricle.

Mitral insufficiency: In each of the 9 cases in which the mitral cleft was the only significant anomaly (Group I), some degree of mitral insufficiency was considered to have been present. Three of the patients died from congestive cardiac failure. This functional disturbance was more difficult to evaluate in those cases having significant anomalies in addition to the mitral cleft. Nevertheless, among the 11 cases with additional anomalies, mitral insufficiency had either been demonstrated clinically or interpreted from the specimen as having been present in 6 cases (3 moderate and 3 mild). Among the remaining 5 cases with additional anomalies, mitral insufficiency was considered not to have been present in each, including the 1 case of corrected transposition and right-sided mitral valve. In the latter case, ventriculography had demonstrated competence of the valve.

Correlations were attempted between the presence or absence of mitral insufficiency and, when present, its degree on one hand, and certain features of the mitral valve on the other (Fig. 9). These were: (1) dimension of the cleft, (2) the width of the base of the anterior leaflet compared with the width of the base of the posterior leaflet, (3) the position of the cleft, and (4) the presence of ectopic chordae.

Ratios were determined of the width of the cleft compared with the width of the base of the anterior leaflet. These ranged from 0.1 to 0.5.

The wider the cleft, the more likely was the presence of mitral insufficiency. With this ratio, a statistically significant difference ($p < 0.025$) was found between subjects with absent or mild mitral insufficiency on one hand, and subjects with moderate or severe mitral insufficiency on the other (Fig. 10).

Ratios were determined for the depth of the cleft compared with the depth of the anterior mitral leaflet. There was no relation between these values and mitral insufficiency.

Ratios were obtained of the width of the entire mitral anulus to the width of the base of the anterior mitral leaflet. These ranged from 1.6 to 2.4. No relation between these ratios and mitral insufficiency was noted.

The position of the cleft was not always central in the anterior leaflet as judged by the fact that the anterior and posterior halves of the leaflet were not always equal. Mitral regurgitation was always found when the anterior portion of the cleft leaflet was larger than the posterior.

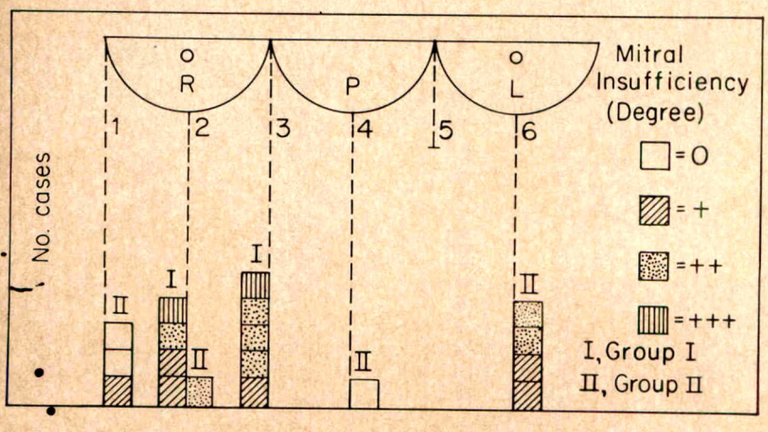

FIGURE 9. Various positions of ectopic chordal insertion as defined in Figure 2, according to the degree of mitral insufficiency. 0 = no mitral insufficiency; + = mild, ++ = moderate, and +++ = severe mitral insufficiency, respectively. The case with l-transposition of the great arteries and a case in which evaluation of mitral insufficiency was not possible are not included.

Symmetrically cleft leaflets or leaflets with a larger posterior component varied as to the presence of mitral insufficiency.

There was no obvious correlation between the site of insertion of accessory chordae on one hand, and mitral insufficiency on the other. This lack of correlation may result from the fact that the presence of the cleft is the primary determinant of mitral insufficiency. Nevertheless, some influence of chordal insertion may have played a role in favoring mitral insufficiency. For example, in Case 3 as shown in Figure 6, a small cleft with anterior insertion of ectopic chordae beneath the commissure between the right and posterior aortic cusps was associated with severe mitral insufficiency.

Left ventricular outflow stenosis: From pathologic examination, narrowing of the left ventricular outflow tract was considered to have been present in 10 cases. This abnormality, among the most severe forms of subaortic stenosis, had been diagnosed clinically in some. Based on our interpretation of the presence or absence of subaortic stenosis, in both Groups I and IIA, left ventricular outflow tract stenosis was determined to be clearly related to the site of septal insertion of accessory chordae, namely into the ventricular septum beneath the right aortic cusp (Fig. 8). In 3 cases, relatively long accessory chordae appeared to have caused a degree of subaortic stenosis which was less than that expected from the position of their septal insertion. In cases with d-transposition of the great arteries (IIB), left ventricular outflow stenosis was rare. In the case with l-transposition of the great arteries (IIC), the narrowing of the outflow tract of the right-sided morphologic left ventricle was caused by accessory tissue of the mitral valve and not by the insertion of accessory chordae.

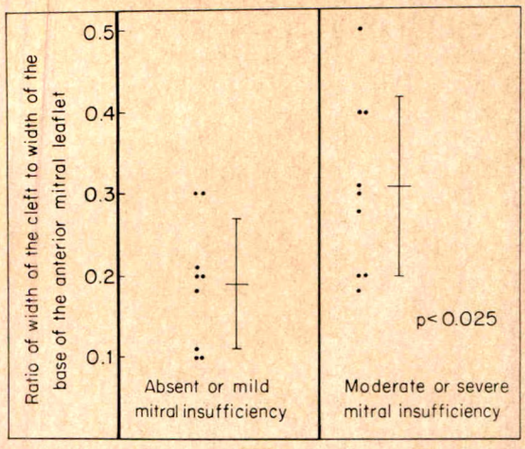

FIGURE 10. Correlation between the ratio of width of the cleft to width of the base of the anterior mitral leaflet and the degree of mitral insufficiency. In subjects with absent or mild mitral insufficiency, the ratio was 0.19 ± 0.8 (standard deviation) and in subjects with moderate or severe mitral insufficiency, the ratio was 0.31 ± 0.12 ($p < 0.025$). Two of the cases in the study are not represented.

Discussion

The anomaly described in this communication consists of a cleft of the anterior mitral leaflet. The cleft may involve a variable length on the anterior mitral leaflet and is usually shaped like an inverted V. As a result of the cleft, the anterior mitral leaflet is divided in anterior and posterior components. Accessory tissue taking the form of chordae, a raphe structure, or both extends from the ventricular aspect of the intact portion of the cleft leaflet to the ventricular septum or the anterior wall of the left ventricle. The latter process may cause left ventricular outflow tract stenosis.

The question might be raised as to whether the cleft is acquired or congenital. Acquired disease giving rise to a defect would, of necessity, be a destructive inflammatory process such as bacterial endocarditis. Militating against this possible cause is the fact that no torn chordae were seen in any of the hearts examined. An important factor favoring a congenital origin is the presence of accessory tissue that attaches to the cleft, either at its apex or along the tissue edging the cleft.

The cleft is of the same type as seen in classic examples of persistent common atrioventricular canal or endocardial cushion defect.[1,4] Thus, the condition of cleft anterior mitral leaflet may be considered a forme fruste of the endocardial cushion defect in which the septal defects that characterize the full picture of the malformation are absent. Additional features related to the endocardial cushion defect may be found in hearts with a cleft in the anterior mitral leaflet. These include abnormally increased ratio of length of left ventricular outflow to inflow tract, "scooped out" deficiency of the ventricular septal summit, cleft of the septal tricuspid leaflet, and double mitral orifice. The association with Down's syndrome in 4 of our 20 cases, a condition frequently associated with the endocardial cushion defect, further stresses the embryologic relation of the isolated cleft mitral valve with endocardial cushion defect.

As far as we are aware, isolated cleft of the mitral valve was first described by one of us (JEE) in 1954.[1] A few reports of examples of this condition have since been reported. We were able to find only 36 cases,[1–21] 9 of which correspond to 9 of our 20 cases.[1,4,10,16–19] Eleven of our cases have not previously been reported. Associated cardiac anomalies were found in 27 of the 36 reported cases to which reference has been made.[4–16,18–21] The most frequent of such anomalies was a fossa ovalis (secundum)-type atrial septal defect (15 cases).[4–9,11–14,20] The unusual association of a secundum-type atrial septal defect with a cleft mitral valve was the source of diagnostic errors, since this defect of the mitral valve is classically associated with an ostium primum atrial septal defect. Other associated anomalies reported were transposition of great arteries,[16–18] tricuspid atresia,[18] pouches of the tricuspid valve,[19] left ventricular-right atrial communication,[19] coarctation of aorta,[7] ventricular septal defect,[7–14] partial anomalous pulmonary venous connection,[15] and double-outlet right ventricle.[21] The tendency of a cleft of the anterior mitral leaflet to be associated with other cardiac malformations is emphasized by the present series.

The scarcity of the reported cases appears to be due to the rarity of the syndrome, as well as to difficulty of the clinical differentiation from other causes of mitral

insufficiency and subaortic stenosis. Most of the reported cases were correctly recognized at operation or at autopsy. The diagnostic value of the electrovectorcardiogram was suggested in the past.[5,6,12,13] A left-axis deviation with counterclockwise rotation of the initial vector on the frontal plane, such as that seen in atrioventricular canal defect,[25,26] was considered a useful sign of mitral valve cleft; but, judging from limited electrocardiographic data in our material, this sign is infrequent in our series.

Angiographic diagnosis of the mitral valve cleft is usually possible in atrioventricular canal defect. However, as far as the isolated mitral valve cleft is concerned, the angiographic demonstration of the cleft was unsuccessful according to the experience of others and in the cases in our material.[7,11–13,15,16] The usefulness of angiography lies in its ability to quantify the mitral insufficiency rather than in its ability to identify its cause.

It has been recently shown that the mitral valve cleft can be precisely imaged by 2-dimensional echocardiography.[22] The finding of a cleft mitral valve is a cardinal echocardiographic sign of atrioventricular canal defect. The echocardiographic diagnosis of cleft of the anterior mitral leaflet in 2 cases associated with double-outlet right ventricle has been reported.[21] We have personal experience with 2 living patients having severe mitral insufficiency and no septal defects as shown by cardiac catheterization whose echocardiograms showed a typical mitral valve cleft and intact atrial and ventricular septa.

Various degrees of left ventricular outflow tract stenosis were interpreted as having been present in about half of our cases.

The condition appears to result from restraint of the anterior mitral leaflet by accessory chordae that attach to the ventricular septum. This phenomenon was described by Sellers et al[17] in 1964. Our cases emphasize the point that cleft mitral valve may simultaneously cause subaortic stenosis and mitral insufficiency. In this way the anomaly described herein must be distinguished from hypertrophic muscular subaortic stenosis.

While the condition represents a "minor" lesion from the embryologic point of view compared with the usual picture of the endocardial cushion defect, in many cases it represents a severe clinical disease which requires surgery early in childhood. The problem of mitral valve surgery in children is obviously avoiding replacement of the valve. Plastic repair of the affected leaflet has been reported in 18 cases of isolated mitral valve cleft.[2,5–8,11–15,20] In the majority of these cases, the results of operation were evidently successful. This experience on a limited number of cases matches the larger experience of repair of cleft valves of atrioventricular canal defects.[27] The rationale for reparative surgery seems well based. Our data show that potentially correctable factors causing mitral insufficiency may be identified. These factors are the width of the cleft and perhaps the septal insertion of ectopic chordae. In the past, the role of these elements was recognized in the cleft mitral valve of persistent common atrioventricular canal.[28] Suture of the cleft and resection of the accessory chordae are probably both necessary for a complete correction of the altered function of the mitral valve.

Isolated Cleft Mitral Valve: A Variety of Congenital Mitral Regurgitation Identified by 2-Dimensional Echocardiography

ELIO DI SEGNI, MD, JOHN L. BASS, MD, RUSSELL V. LUCAS, Jr., MD, and STANLEY EINZIG, MD, PhD

Nine children with isolated cleft mitral valve, aged 1 day to 12 years, were studied. The electrocardiogram showed a normal QRS axis in 5 subjects. Cardiac catheterization was performed in 4 patients and demonstrated severe mitral insufficiency in 3 but failed to clearly demonstrate a cleft mitral valve or gooseneck deformity. The mitral cleft was confirmed at operation in 2 patients.

Two-dimensional echocardiography demonstrated a cleft dividing the anterior mitral leaflet into 2 portions in each patient. The mitral anulus was normally positioned and the atrioventricular septum present. Atrial and ventricular septa were intact. Features similar to anatomic studies such as accessory chordae and thickening of the edges of the cleft with increasing age were also seen. Two-dimensional echocardiography is the only method available to reliably diagnose isolated cleft of the mitral valve.

Cleft anterior leaflet of the mitral valve is usually associated with atrial or ventricular septal defects of persistent atrioventricular canal (endocardial cushion defect) type. As an isolated anomaly, cleft mitral valve is a rare cause of mitral regurgitation (MR).[1-11] The clinical and angiographic differentiation of this condition from other causes of MR is difficult. Most reported cases have been diagnosed at operation or at autopsy. Two-dimensional (2-D) echocardiography precisely images the anatomy of the mitral valve, and findings of cleft mitral valve associated with other forms of endocardial cushion defect have been described.[12,13] We identified 9 children with cleft mitral valve and intact atrial and ventricular septa using 2-D echocardiography. This study reports the echocardiographic, clinical, and hemodynamic findings in these patients.

Methods

Nine patients, 6 female and 3 male, aged 1 day to 12 years, were studied (Table I). Twelve-lead electrocardiograms and thoracic roentgenograms were obtained in all patients. Cardiac catheterization was performed in 4 patients (Table II). MR was graded on a scale from 1+ to 4+ by cine left ventriculography.[14] In 2 patients (Cases 2 and 3), the diagnosis was confirmed at operation.

Two-dimensional echocardiograms were performed with a Smith Kline Instruments mechanical sector scanner using a 30° or 80° 5 MHz transducer or with an Advanced Technology Laboratories mechanical sector scanner using an 80° 5 MHz transducer. In each patient, standard parasternal, subcostal, and apical views were obtained and recorded on video tape.

Results

One patient (Case 9) had 3 siblings with partial atrioventricular canal defect. Seven patients were asymptomatic including 3 infants, 1 of whom had trisomy 21 (Case 6). A 6-year-old girl (Case 2) had severe exercise intolerance and orthopnea. A 12-year-old boy (Case 4) complained of decreased exercise tolerance after age 6. The first and second heart sounds were normal in all patients. An apical pansystolic murmur (grade 2/6 to 4/6) radiating to the axilla and the back was heard in all patients. A third heart sound was heard in 4 subjects; in 3, it preceded a mid-diastolic rumbling murmur. Electrocardiograms showed a prolonged P-R interval in 3 patients (Table I). The QRS axis was normal in 5 patients, and in the remaining 2 patients it was 0° to −120°. Signs of left atrial enlargement and left ventricular hypertrophy were present in 2 patients. One patient had electrocardiographic evidence of biventricular hypertrophy. Thoracic roentgenograms showed an enlarged left atrium in 4 patients, left ventricular enlargement in 3 and pulmonary venous congestion in 2. Five patients had normal findings on roentgenography.

9	M	11 years	0.18	+60°	0	0	0

+ = present; 0 = absent.

Cardiac catheterization (Table II) was performed in 4 patients. Three patients had a clinical diagnosis of MR and radiographic evidence of cardiomegaly; 2 of these were symptomatic. The fourth patient was initially referred for cardiac catheterization with a clinical diagnosis of complete atrioventricular canal defect, with a normal thoracic roentoenogram and no symptoms. No oximetry or angiographic evidence of an intracardiac left-to-right shunt was found in any patient. Pulmonary arterial wedge pressure was increased in 2 patients. A 10 mm Hg peak systolic pressure difference between the left ventricle and the aorta was found in 1 patient (Case 4).

At cine left ventriculography, severe MR was found in 3 patients (Cases 2, 3, and 4); in 2 (Cases 2 and 4), prolapse of a portion of the mitral valve was present. The fourth patient (Case 1) had no MR, but radiolucent structures were identified in the left ventricular outflow tract during systole. These structures were interpreted as representing accessory mitral valve tissue. No patient had a gooseneck deformity or a clearly seen cleft of the mitral valve anterior leaflet. The atrial and ventricular septa were intact in all 4 patients.

Surgery was performed in 2 patients (Cases 2 and 3). In Patient 2, the cleft in the anterior leaflet extended to the anulus and divided the leaflet into 2 unequal parts (Fig. 1). This cleft was easily closed with interrupted sutures resulting in a pliable leaflet that guarded two thirds of the mitral orifice and created no stenosis. The scallops of the posterior leaflet were small, thickened, had rolled edges, and moderate prolapse. These scallops did not coapt with the anterior leaflet. The resultant MR was deemed excessive and therefore the mitral valve was resected and replaced with a Björk-Shiley prosthesis. The patient had an uneventful recovery. Her exercise tolerance improved and cardiac size seen in the thoracic roentgenograms was significantly reduced. Surgical findings in Patient 3 were similar, although the rolling and thickening of mitral valve tissue was less marked. Suture closure of the mitral cleft resulted in a competent mitral valve.

With the exception of accessory mitral valve tissue in Patient 1, the echocardiographic appearance of the mitral valve was similar in all 9 patients, and will be discussed together. In these patients, the mitral valve was well seen in the standard short-axis orientation, rather than the more vertical short-axis plane which has been suggested for demonstrating the mitral cleft in endocardial cushion defect.[13] The parasternal short-axis view demonstrated the cleft anterior mitral leaflet better than the subcostal short-axis view in 8 patients. In 1 newborn infant the cleft leaflet was better seen on subcostal images. During diastole, the anterior mitral leaflet separated widely into medial and lateral portions in all patients (Fig. 2). In 7 patients, the anterior edges of the cleft mitral leaflet apposed the ventricular septum. The portions of the anterior leaflet were similar in width in 4 patients. In the other 5, the lateral portion of the leaflet was wider than the medial (Fig. 2). The anterior leaflet appeared normal in thickness in all patients. However, the edges of the cleft appeared thickened and rolled toward the left ventricle in all patients except the 3 infants (Cases 5, 6, and 7).

In systole the anterior mitral leaflet formed a continuous echo in 8 patients. In 1 patient (Case 3) a gap of about 2 mm between the 2 portions of the anterior

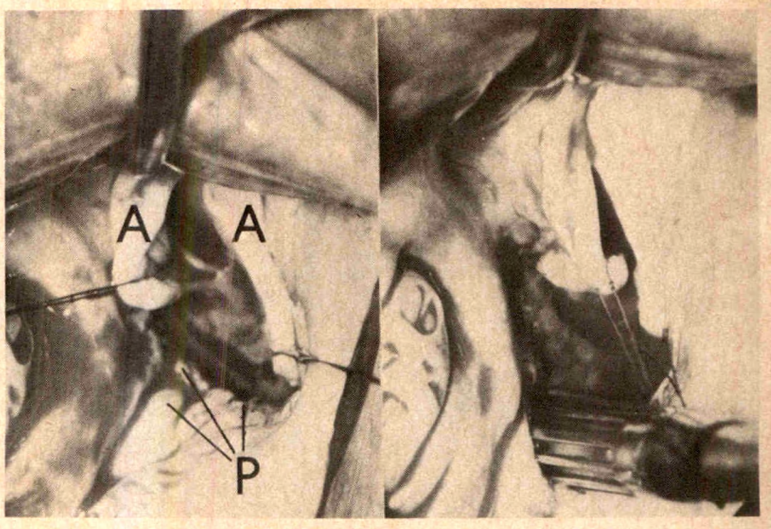

FIGURE 1. Case 2. Mitral valve viewed from above at the time of operation. **Left,** a cleft divides the anterior leaflet into similar segments (A). The scallops of the posterior leaflet of the mitral valve (P) are thickened, have rolled edges, and are small. **Right,** the 2 components of the cleft mitral valve are pulled together by the stay sutures. The cleft is complete to the level of the anulus. There is adequate anterior leaflet tissue for repair. The repaired anterior leaflet guarded approximately two thirds of the mitral valve orifice.

leaflet persisted in systole. Two patients (Cases 2 and 4) had a mild degree of mitral valve prolapse.

Linear echoes extending from the coaptation line of the cleft anterior leaflet to the upper portion of ventricular septum (Fig. 3) were seen in 3 subjects (Cases 2, 4, and 6). These echoes probably represent accessory chordal attachments from the mitral valve to the ventricular septum as have been noted in autopsy studies.[17] The 3 patients with echocardiographic evidence of accessory chordae tendineae also had systolic anterior bending of the basal portion of the anterior leaflet. This was interpreted as resulting from restraint of motion of the anterior mitral leaflet by the accessory chordae. As a result of the presence of accessory chordae and of the systolic anterior bending of the mitral valve, the left ventricular outflow tract appeared narrow on the echocardiograms of all 3 patients (Fig. 3). However, this was not associated with significant hemodynamic abnormalities in the 2 patients in whom cardiac catheterization was performed.

Atrial and ventricular septal defects were not detected with echocardiography in any patient. Mitral and tricuspid valve anuli were at different levels in all patients (Fig. 4). Thus, the atrioventricular septum (shared by the left ventricle and right atrium), which is between the anuli of the atrioventricular valves, was demonstrated in all subjects.

Two patients had echocardiographic abnormalities besides those involving the mitral valve. In one (Case 1), multiple echoreflective structures that protruded into the left ventricular outflow tract during systole and appeared to be attached to the mitral valve apparatus were recorded. These corresponded to angiographic findings suggesting accessory mitral valve tissue. In the other patient (Case 7), multiple echoes were recorded from the aortic valve which domed during systole,

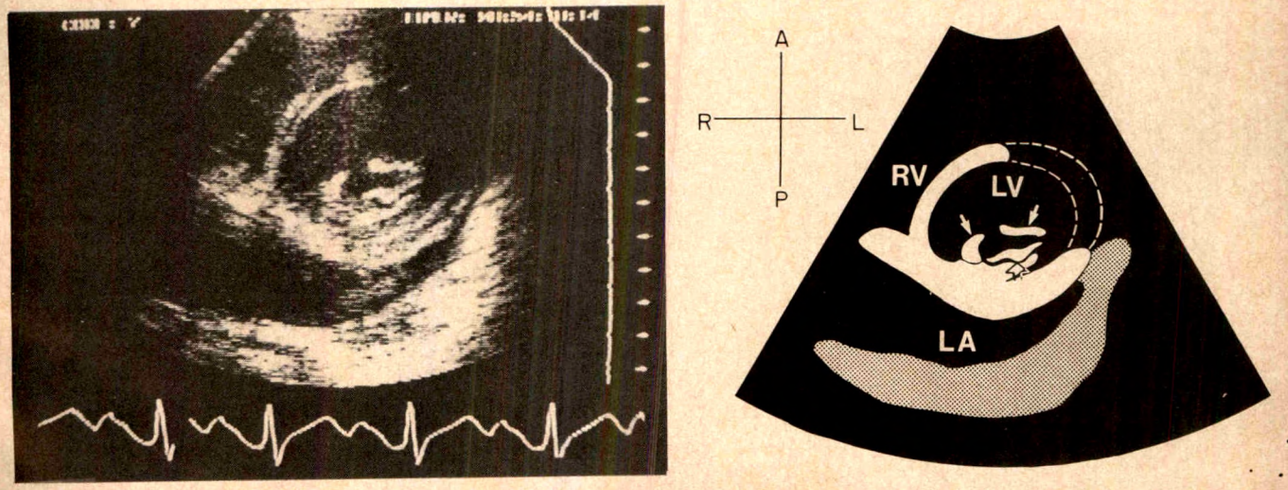

FIGURE 2. Case 2. Two-dimensional echocardiogram in the parasternal short-axis view, and corresponding schematic drawing. A cleft divides the anterior mitral leaflet into 2 portions of different size (**solid arrows**). The posterior mitral leafet (**open arrow**) is behind the cleft anterior leaflet. The echo-free space behind the left ventricle (LV) is an extension of the markedly enlarged left atrium (LA). A = anterior; L = left; P = posterior; R = right; RV = right ventricle.

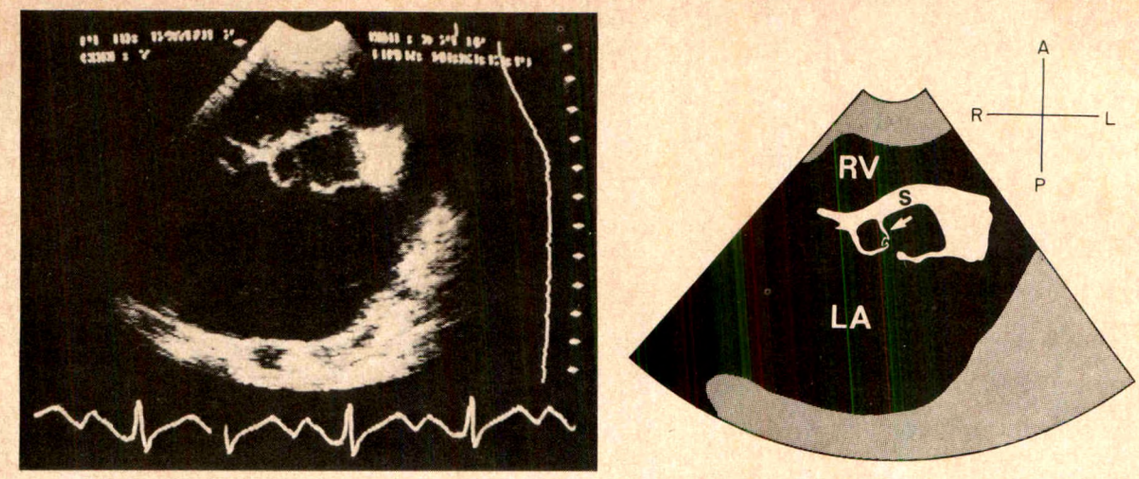

FIGURE 3. Case 2. Two-dimensional echocardiogram in the parasternal short-axis view and corresponding schematic drawing. A thin linear echo representing an accessory chorda (**arrow**) extends from the coaptation point of the halves of the anterior mitral leaflet to the upper portion of the interventricular septum (S). Mild narrowing of the left ventricular outflow tract results from the presence of the accessory chorda. Abbreviations as in Figure 2.

suggesting an abnormal aortic valve. This patient also had an apical systolic ejection click.

Discussion

The anatomic aspects of cleft mitral valve without septal defects of the endocardial cushion defect type (so-called isolated cleft of the mitral valve) have been recently reviewed in a study of 20 hearts.[15] In this anatomic study, the mitral anulus was normally located. The cleft extended for a variable depth on the anterior mitral leaflet except at its base, where the leaflet was undivided. The cleft divided the anterior leaflet into 2 equal portions in 8 specimens, whereas in the others the medial and lateral portions of the anterior leaflet were of different widths. The mitral leaflet was normally thin and smooth in patients younger than 2 years of age. In patients older than 4 years of age, the edges of the cleft were thickened by fibrous tissue in all cases. Accessory chordae tendineae extended from the apex of the cleft or, rarely, from the edges of the cleft to the ventricular septum or anterior wall of the left ventricle.

These anatomic features of isolated cleft mitral valve were demonstrated by 2-D echocardiography in the 9 patients we studied. The normal position of the mitral valve anulus was confirmed by the absence of a deficiency (so called scooping out) of the crest of the ventricular septum. In no patient were the mitral and tricuspid valve anuli at the same level on the crest of the ventricular septum. In contrast, the atrioventricular septum, characteristically absent in ostium primum defect with or without associated ventricular septal defect[16] was demonstrated in each of our patients. Moreover, the mitral valve was well seen in the usual short-axis plane. This is in contrast to the vertical or-

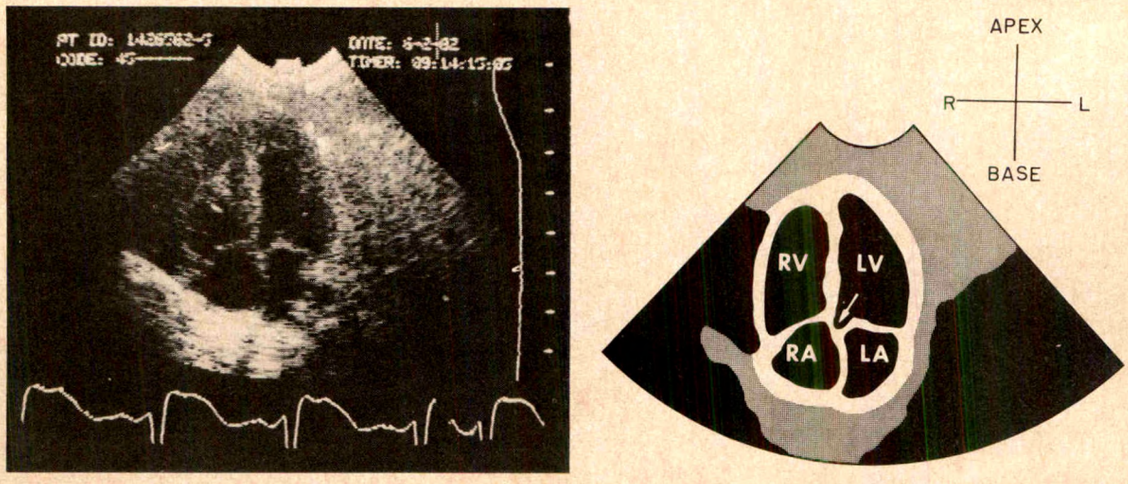

FIGURE 4. Case 6. Two-dimensional echocardiogram in the apical 4-chamber view and corresponding schematic drawing. The atrial septum and the ventricular septum are intact. The atrioventricular septum (**arrow**) is between the mitral and tricuspid annuli. RA = right atrium; other abbreviations as in Figure 2.

ientation of the echocardiographic cross section required for optimal visualization of the cleft mitral leaflet in other forms of endocardial cushion defect.[13] In isolated mitral cleft, the mitral anulus is in a normal position and the cleft points toward the left ventricular outflow tract; in other forms of persistent atrioventricular canal, the mitral anulus is vertically oriented and the cleft points toward the ventricular septum.[17] The basal portion of the anterior leaflet appeared intact in the echocardiogram in all instances. The relative widths of the portions of the cleft leaflet were easily recognized. The age distribution of the echocardiographic appearance of thickening and rolling of the edges of the cleft paralleled that of the anatomic study.[15] Only in the 3 infants (Cases 5, 6, and 7) did the edges of the cleft appear thin. Moreover, in 3 patients accessory chordae tendineae were demonstrated.

To confidently make an echocardiographic diagnosis of isolated cleft of the mitral valve, one must exclude associated septal defects of the endocardial cushion defect type. The sensitivity of 2-D echocardiography in detecting septal defects of the endocardial cushion defect type is high. In the series described by Hagler et al,[12] ostium primum atrial septal defect was detected with 2-D echocardiography in each of 42 cases and ventricular septal defect in 27 of 28 cases. None of the 9 patients we examined had echocardiographic evidence of septal defects. This is supported by the absence of clinical or roentgenographic findings of a left-to-right shunt. Oximetric and angiographic documentation of intact atrial and ventricular septa were obtained in 4 cases, and confirmed at surgery in 2.

Before echocardiography was available, the clinical diagnosis of this entity was extremely difficult. Most patients reported on were diagnosed only at operation or autopsy. It has been stated that in patients with MR or even ostium secundum atrial septal defect, the finding of electrocardiographic left-axis deviation might suggest the diagnosis of cleft mitral valve.[11] However, of reported cases of isolated cleft mitral valve, left axis deviation was found only in 33%.[1,2,4,6,7,9–11] Five of our 9 patients had a normal QRS axis.

Angiographic demonstration of isolated mitral cleft was usually unsuccessful in reported cases. In the 4 patients we examined with angiography, demonstration of the cleft was questionable, and there was no evidence of the gooseneck deformity classic of other forms of endocardial cushion defect. Two-dimensional echocardiography is extremely sensitive in demonstrating the cleft of the mitral valve anterior leaflet when it is associated with a primum atrial septal defect.[12,13] When corrected transposition is not present, this echocardiographic appearance is always associated with a cleft of the mitral valve.

Two-dimensional echocardiography has the specific capacity to differentiate cleft mitral valve from other causes of MR. The importance of this echocardiographic diagnosis is heightened by the relative insensitivity of electrocardiography and angiography. Two-dimensional echocardiography may, therefore, be of help in identifying a subgroup of patients with congenital MR in whom repair of the mitral valve may be feasible without replacement.[17] This is of great importance especially in pediatric patients in whom replacement of the mitral valve carries a substantial morbidity and mortality.[18]

Pulmonary Atresia With and Without Ventricular Septal Defect: A Different Etiology and Pathogenesis for The Atresia in the 2 Types?

LYNN M. KUTSCHE, MD and L. H. S. VAN MIEROP, MD

In 15 of 20 hearts of neonates with pulmonary atresia and intact septum (PA-IVS) and in 4 with critical pulmonary stenosis, the pulmonary valve consisted of 3 fused cusps. One of the 11 patients with a ventricular septal defect (PA-VSD) had a well-developed pulmonary root; in 8 the pulmonary trunk arose from a dimple. Two had a bicuspid valve.

In 10 of the 20 patients with PA-IVS and in those with critical stenosis, the diameter of the pulmonary trunk was normal or larger than normal. The authors believe that this is related to flow through an initially patent pulmonary valve and, perhaps more importantly, to poststenotic dilatation. In all hearts with PA-VSD, the pulmonary trunk was very small. In the patients with PA-IVS and a normal-sized pulmonary trunk and in 3 with critical pulmonary stenosis, the morphology of the ductus arteriosus was normal, suggesting that even in the former the valve was patent before birth, allowing forward flow. In all patients with small pulmonary trunk, the ductus was long, tortuous, and originated from the aortic arch in a proximal position, suggesting that reversal of flow had occurred early in development.

The authors postulate that in patients with ventricular septal defect (VSD), the pulmonary ostium becomes atretic early in development, at or shortly after partitioning of the truncoconal part of the heart has taken place but before closure of the ventricular septum. In patients with intact ventricular septum, on the other hand, atresia very likely occurs sometime after cardiac septation has been completed. In these cases the pulmonary atresia may be due to a prenatal inflammatory process, rather than representing a true congenital malformation.

The usually small to very small size of the pulmonary trunk in patients with pulmonary atresia associated with a ventricular septal defect (PA-VSD) has rarely evoked comment, presumably because it seems logical and is to be expected that in the absence of any blood flow an artery does not develop a significant caliber. In some cases the pulmonary trunk may even be reduced to a fibrous strand. Many investigators,[1–5] however, have commented upon the unexpectedly large size of the pulmonary trunk when pulmonary atresia occurs with an intact ventricular septum (PA-IVS). This and other striking differences between cases of pulmonary atresia with and those without ventricular septal defect (VSD) we believe to be due to different antenatal hemodynamic features that may provide important clues as to the pathogenesis of pulmonary atresia in the 2 groups.

Methods

Thirty-one hearts with pulmonary atresia and 4 with critical pulmonary stenosis from infants <1 month old were available for study. In 20 patients with pulmonary atresia and in the 4 with critical stenosis, the ventricular septum was intact; in the other 11 there was an associated VSD. Four normal hearts from full-term infants of the same age group were used as controls for the measurements. Each specimen had been fixed in the distended ("diastolic") state, as is customary in our laboratory. For this purpose a cannula is tied in the superior vena cava and, in cases in which the cardiac septum is intact, also in the left upper pulmonary vein. All other vessels entering and leaving the heart are closed by ligation or placement of an appropriate size cork. The heart is submerged in alcoholic formalin and the same fixative is run into the heart through the cannula(s) at a pressure of about 20 cm of water.

After fixation, the cardiac chambers and great arteries are opened by the creation of appropriate windows. In the present study, the diameters of the ascending aorta and the pulmonary trunk were measured midway between the aortic valve and the brachiocephalic (innominate) artery and between the pulmonary trunk and the pulmonary bifurcation, respectively. The diameter of the descending aorta was measured distal to the ductus arteriosus.

Results

In Table I are listed mean heart weights and diameters of the pulmonary trunk, ascending aorta, isthmus,

and descending aorta, as well as the corresponding cross-sectional areas and the ratios between pulmonary trunk and descending aortic diameters.

Normal newborn hearts: The observations in the 4 normal hearts essentially agree with those reported by others.[6–9] The normal pulmonary trunk at birth is slightly larger than the ascending aorta. The ductus arteriosus is normally quite short; its long axis runs parallel to that of the aortic arch, and it joins the descending portion of the aortic arch distal to the origin of the left subclavian artery (Fig. 1). At birth the segment of aortic arch between the left subclavian artery and the ductus is narrower than the remainder of the arch and than the descending aorta, hence the name "isthmus."

Pulmonary valvular atresia or critical stenosis and intact ventricular septum: *Pulmonary valvular atresia with intact ventricular septum:* In 15 of the 20 cases, the fused pulmonary cusps were quite well developed. In 14 of these, the valve was tricuspid and had the typical triradiate appearance described by many investigators[1–4,10–14] (Fig. 2); in 1 it was quadricuspid. In the remaining 5 cases, the pulmonary trunk originated proximally from a dimple and there was no evidence of a pulmonary root.

The mean diameter of the pulmonary trunk was 75% of normal (Table I). The diameter of the ascending aorta was significantly greater than normal. That of the descending aorta, however, was within the normal range. The diameter of the isthmus was intermediate between that of the ascending and descending aorta, that is, an actual isthmus was not present. In 2 cases, the isthmus could not be measured because the aortoductal junction was at or proximal to the origin of the left subclavian artery.

The ductus arteriosus was patent in all cases. In 8 its structure was normal (Fig. 3A). In all 8 cases the pulmonary trunk diameter was ≥8 mm, well within the normal range. In 3 of these it was actually greater than normal (10, 11, and 11 mm). In 9 others, the ductus was abnormally long and had the appearance of an artery arising from, rather than joining, the aortic arch. Its point of origin was further proximal than that of the normal aortoductal junction (Fig. 3B). It diverged from

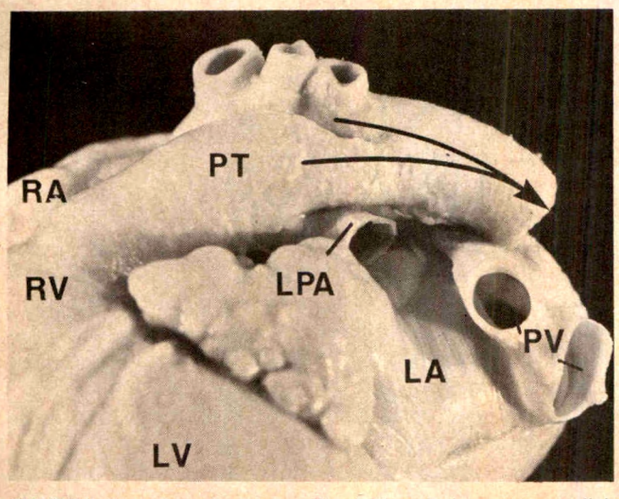

FIGURE 1. Normal newborn heart. The ductus arteriosus runs parallel to the aorta and joins the aorta at an acute angle. **Arrows** indicate direction of blood flow. LA = left atrium; LPA = left pulmonary artery; LV = left ventricle; PT = pulmonary trunk; PV = pulmonary veins; RA = right atrium; RV = right ventricle.

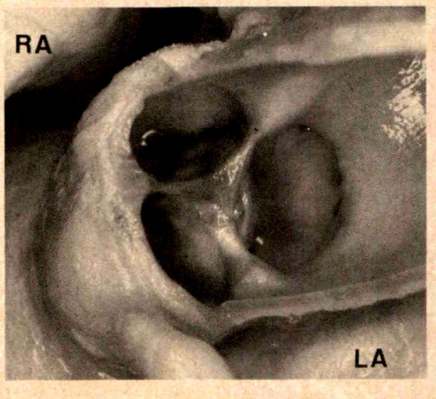

FIGURE 2. Pulmonary valve in a case of pulmonary atresia with intact ventricular septum. The sinuses of Valsalva and the valve cusps are well developed. LA = left atrium; RA = right atrium.

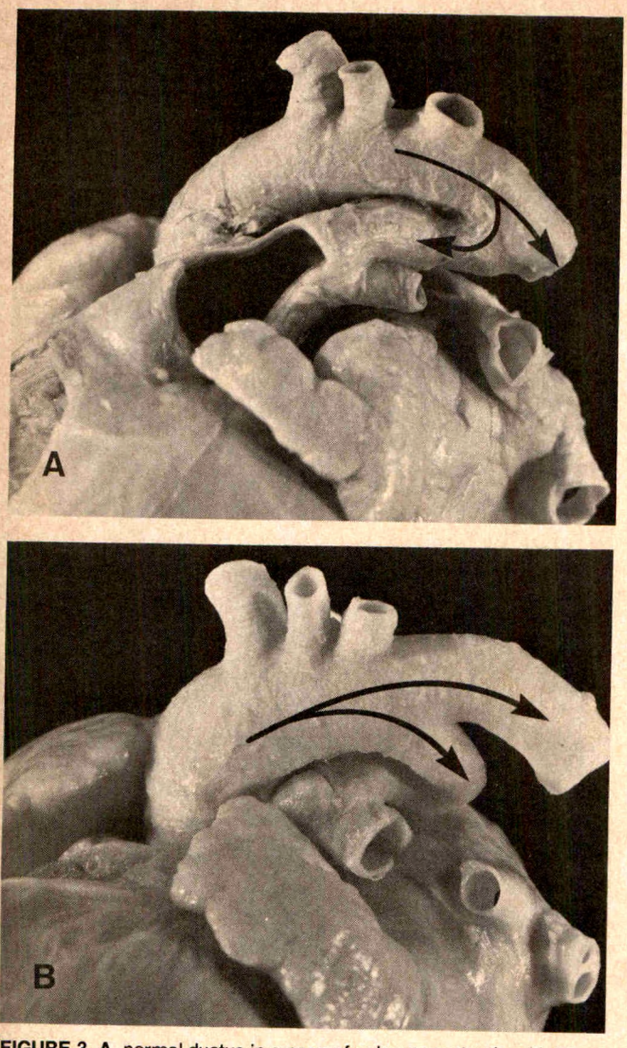

FIGURE 3. A, normal ductus in a case of pulmonary atresia with intact ventricular septum. The pulmonary trunk to descending aorta ratio was 1.5. **B,** sigmoid-shaped ductus in a case which had a pulmonary trunk to descending aorta ratio of only 0.3.

the aortic arch at an acute angle and then, turning back on itself, joined the left pulmonary artery at or near the bifurcation of the pulmonary trunk. In all these cases with a sigmoid-shaped ductus, the diameter of the pulmonary trunk was ≤6 mm. In the remaining 3 hearts, the ductus resembled the normal but joined the distal aortic arch at an angle of about 90°, that is, its structure was intermediate. The pulmonary trunk diameter in these cases was in or below the normal range.

The right ventricular cavity was small to very small ("peach-pit" right ventricle) in 4 of the 8 cases with normal ductus, in 7 of 9 with a sigmoid ductus, and in 2 of 3 with an intermediate-type ductus. In only 7 of the 20 cases was it normal or larger than normal.

Critical pulmonary valvular stenosis with intact ventricular septum: The morphology of these hearts was almost identical to that of the previous subgroup. The pulmonary valve was triradiate but had a pinpoint opening. The pulmonary trunk diameter in all 4 of our cases was greater than normal (Table I), as was the diameter of the ascending aorta. The descending aortic diameter fell within the normal range. As in PA-IVS, the diameter of the isthmus was intermediate between the ascending and descending aorta. In 1 of the 4 cases, the ductus arteriosus was sigmoid-shaped and originated from the aortic arch proximal to the left subclavian artery. In this case the right ventricle was small; in the others it was nearly normal.

Pulmonary valvular atresia with ventricular septal defect: This anomaly we consider to be a form of tetralogy of Fallot in which the pulmonary valve or ostium has become atretic. In 8 of the 11 cases, the pulmonary trunk originated proximally from a dimple; in 2 cases there was a bicuspid valve with fused cusps. Only 1 case had an essentially tricuspid valve. Two of the 11 hearts weighed <18 g and were not used for measurements of arterial diameters, only for ratios and morphologic characteristics. The mean diameter of the pulmonary trunk in the other 9 hearts was much smaller than normal, while that of the ascending aorta was abnormally large, similar to that seen in cases of PA-IVS (Table I). The diameter of the descending aorta was normal. The isthmus could be measured in only 2 cases: it was wider than the descending aorta in both. In the other 9 cases, the origin of the ductus was at or proximal to that of the left subclavian artery, or the ductus arteriosus arose from the brachiocephalic (innominate) artery on the side opposite the aortic arch, that is, there was no isthmus. The ductus was long, narrow, and sigmoid-shaped in all 11 cases. The right ventricular cavity was of normal size in all cases.

Discussion

The strikingly large size of the pulmonary trunk in many if not most cases of PA-IVS would be found even more prevalent than reported if its diameter were compared with that of the descending aorta rather than with that of the ascending aorta as is usually done[1,4,11,14]—the latter is always abnormally large whenever there is marked reduction in pulmonary blood flow due to severe pulmonary stenosis or atresia.[15]

Why then is the pulmonary trunk usually relatively large when pulmonary atresia or critical stenosis is associated with an intact ventricular septum and almost invariably small to very small when there is a ventricular septal defect?[2,3,12,16–18] Why is the atretic pulmonary valve in the former tricuspid and may be almost normally formed, while it is nearly always morphologically abnormal or merely represented by a dimple in the latter? Finally, why is the ductus arteriosus usually normal if the pulmonary trunk is large, but is long and tortuous, appearing to originate in an unusually proximal position from the aorta as a branch artery rather than joining it as a parallel vessel of equal rank, if the pulmonary trunk is small?

We agree with Santos et al[19] that these questions can be answered very satisfactorily if the prenatal hemodynamics and certain associations of anomalies are taken into consideration. The relatively large size of the pulmonary trunk in most cases of PA-IVS must mean that an anterograde, that is, normally directed flow of blood was present for much or even most of prenatal life through a patent, though stenotic (or perhaps initially

even nonstenotic) pulmonary valve. However, we believe that a second and probably more important contributing factor responsible for the reasonably large and in some cases even abnormally large size of the pulmonary trunk may be the development of poststenotic dilatation during prenatal life. All 4 of our cases of critical pulmonic stenosis had an abnormally large pulmonary trunk, even the 1 with a small right ventricle and sigmoid ductus. The large pulmonary trunk in this case is difficult to explain by a mechanism other than poststenotic dilatation, since the sigmoid-shaped ductus strongly suggests marked and early reduction of right ventricular forward flow.

The normal appearance of the ductus arteriosus in many cases we consider additional evidence that direction of blood flow once was normal and, therefore, that the pulmonary valve had been patent for some period of time before birth.[19]

On the other hand, the abnormal appearance of the ductus in other cases of severe pulmonary stenosis or atresia with intact ventricular septum and in all cases of PA-VSD indicates that the pulmonary valve became atretic early in development and that the ductus functioned as an aortic tributary which carried blood *from* the aorta to the lungs, rather than from the right ventricle and pulmonary trunk *to* the aorta, as does the normal ductus. It is long because it first runs distally, diverging from the aortic arch (a hemodynamically induced morphologic adaptation), then turns back to join the proximal left pulmonary artery. It is narrow because it only has to carry blood to the lungs (5 to 10% of combined ventricular output) rather than most of the right ventricular output (55 to 60% of combined output) as does the normal ductus.[20] This type of ductus arteriosus was present in 21 of 27 cases of pulmonary atresia with VSD reported upon by Donkers,[21] but in only 3 of 13 cases without a VSD. It was present in all 6 cases of PA-VSD reported by Santos et al,[19] but in only 1 of 8 cases in which the ventricular septum was intact. This radical departure from normal morphologic development of the distal left sixth arch again must have taken place at an early embryonic age, before histologic development had advanced to a point that would make remodeling of the vessel impossible. Among our cases of pulmonary atresia, a sigmoid-shaped ductus and a small pulmonary trunk were always associated.

We conclude that the pathogenesis of the pulmonary atresia in cases associated with a VSD probably is different from that of PA-IVS. In the former the VSD, the usually absent or abnormally formed pulmonary valve, the small pulmonary trunk, and the abnormal ductus arteriosus strongly suggest that the pulmonary atresia is part of a "true" congenital cardiac anomaly, that is, due to a fundamental derangement of cardiac development. We consider the anomaly to be a form of tetralogy of Fallot which is believed by many to be due to unequal partitioning of the trunco-conal part of the heart at the expense of the right ventricular outflow tract, the pulmonary root, and the pulmonary trunk.[22–24] The anomaly therefore manifests itself at a very early gestational age and the pulmonary valve almost certainly becomes atretic at about the same time. In PA-IVS, on the other hand, the intact ventricular septum, the near-normal appearance of the pulmonary valve, the usually large, in some cases even abnormally large, pulmonary trunk, and the often normal ductus arteriosus suggest not only that the pulmonary atresia developed at a later gestational age and at a more variable time, but that in fact it may not represent a true developmental error at all (at least not always), but may be an acquired lesion, for example, due to an intrauterine inflammatory process ("fetal endocarditis") as was suggested many years ago by Abbott,[25] and more recently by Rudolph[20] and Wagner.[26]

Acknowledgment: We would like to express our appreciation to Lynne M. Westenfield, who typed the several drafts of the manuscript, and to D. Allen Tucker, Learning Resources Department, who photographed the specimens.

Pulmonary Vein Wedge Angiography: Indications, Results, And Surgical Correlates in 25 Patients

ROBERT M. FREEDOM, MD, GIACOMO PONGIGLIONE, MD, WILLIAM G. WILLIAMS, MD, GEORGE A. TRUSLER, MD, C. A. FREDERICK MOES, MD, and RICHARD D. ROWE, MD

Pulmonary vein wedge angiography was applied to 25 patients ranging in age from 4 months to 16 years. The indications for this technique include (1) determination of the presence or absence of central (intrapericardial or mediastinal) pulmonary arteries in patients with pulmonary atresia where standard anterograde injections of contrast medium do not demonstrate these, (2) determination of the patency and caliber of a nonvisualized pulmonary artery when there is distal "occlusion" by a systemic-to-pulmonary artery anastomosis, (3) determination of the patency and caliber of a nonvisualized pulmonary artery when previous pulmonary arterial banding has led to acquired pulmonary artery atresia, and (4) determination of the presence of a mediastinal pulmonary artery in patients with so-called isolated congenital unilateral absence of a pulmonary artery. Surgical correlates to the interpretation of pulmonary vein wedge angiograms are provided in 18 patients. The present data suggest that pulmonary vein wedge angiography is a safe technique that provides considerable information about (1) the caliber of the parenchymal pulmonary arteries, (2) their sizes at the hilum of the lung, and (3) the presence or absence of a mediastinal confluence of pulmonary arteries. This technique may also complement those anatomic findings derived from anterograde injection of contrast material in patients with pulmonary atresia of a congenital or acquired nature.

The surgical management of patients whose pulmonary arteries are discontinuous from the ventricular mass depends in part on adequate visualization and quantification of the central or mediastinal pulmonary arteries.[1–11] Pulmonary vein wedge angiography has proven an effective technique in demonstrating the true mediastinal (intrapericardial) pulmonary arteries (when present) when standard anterograde injections do not suffice.[12–14] From the reports of Takamiya et al[12] and others, it is clear that pulmonary vein wedge angiography has been applied primarily to patients with pulmonary atresia and ventricular septal defects. This report extends the anatomic indications for pulmonary vein wedge angiography and provides data regarding the surgical outcome of patients who required this procedure.

Indications

We have defined 4 conditions in which pulmonary vein wedge angiography is indicated: (1) The most common indication is the delineation of so-called central (intrapericardial or mediastinal) pulmonary arteries in those patients whose pulmonary arteries are not in perforate continuity with the ventricular mass. Before pulmonary vein wedge angiography is performed, however, ventricular angiography, aortography in the ascending and descending thoracic aorta, and selective injection of bronchial arteries or other aortopulmonary collaterals will have failed to provide visualization of the central pulmonary arteries. (2) A systemic-to-pulmonary artery surgical anastomosis has the potential to completely occlude the pulmonary artery.[15,16] The technique has been used to provide information about the patency and caliber of the nonvisualized distal pulmonary artery. (3) Pulmonary arterial banding may also occlude the pulmonary artery. This can occur when the main pulmonary artery is banded, but distal migration of the band compromises (and indeed may occlude) the origin of 1 pulmonary artery (usually the right).[17,18] Similarly, if bilateral pulmonary artery bands are applied (as for truncus arteriosus), again there is the potential for acquired unilateral absence of a distal pulmonary artery. (4) Finally, we have applied this technique to patients with so-called isolated congenital absence of 1 pulmonary artery.[19]

Technique: The pulmonary vein is probed either through a preexisting interatrial communication, by way of an intact

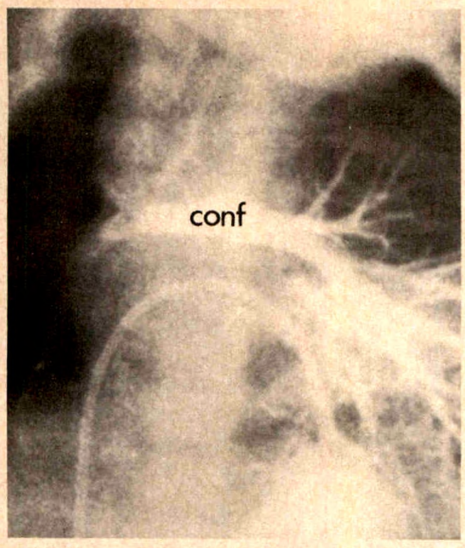

FIGURE 1. Confluent (conf) pulmonary arteries demonstrated by left pulmonary vein wedge angiography in a patient with pulmonary atresia and ventricular septal defect. Left pulmonary vein wedge injection shows confluent right and left pulmonary arteries but with an absent main pulmonary artery.

atrial septum using transseptal technique, or by using a retrograde arterial approach. When this last avenue is utilized (and assuming atrioventricular concordance), the retrograde arterial catheter is advanced to the left ventricle, through the mitral valve, and into the left atrium and pulmonary vein. An end-hole catheter is wedged in the appropriate pulmonary vein. We recommend the injection of 0.4 ml of contrast medium/kg body weight; this is injected at from 2 to 4 ml/s, with a maximal pressure of from 150 to 300 lb/in.^{2} We routinely hand-flush about 1.0 ml saline solution/kg body weight if the contrast material does not immediately reflux into the central or mediastinal pulmonary arteries. The cineangiograms are filmed at 60 frames/s. For 10 minutes before, during, and after pulmonary vein wedge angiography, the patient is given supplemental oxygen by facemask. One-cm calibration grids are routinely used at the end of the cineangiographic run to quantitate the pulmonary arteries.

Results

Twenty-five patients underwent pulmonary vein wedge angiography at the Hospital for Sick Children in Toronto from 1978 through April 1982. Nine were boys and 16 were girls. The age at pulmonary vein wedge angiography for the entire group ranged from 4 months to 16 years (median 6.95 years).

Group 1: All patients in this group had pulmonary atresia. Fifteen patients ranging in age from 4 months to 16 years (mean 6.5 ± 5.8 years; median 6.6) at the time of pulmonary vein wedge angiography comprise this group. No to 3 catheter studies had been performed before pulmonary vein wedge angiography (mean 1.06 ± 0.91). The pulmonary vein wedge injection in 14 patients was performed during the last study before consideration of surgical intervention. One patient underwent pulmonary vein wedge injections at 2 separate catheter investigations 34 months apart. The weight of these patients ranged from 5.3 to 54.6 kg (mean 19.9 ± 16.2, median 18.1).

Bilateral pulmonary vein wedge injections were performed in 4 patients; 3 patients underwent only right-sided injections and the remaining 8 patients had left-sided injections. One to 3 pulmonary veins were injected in each patient (mean 1.56 ± 0.7).

A true confluence (so-called seagull configuration) of right and left pulmonary arteries was demonstrated in 2 patients (13%) (Fig. 1 and 2), while in the remainder a confluence of mediastinal (intrapericardial) pulmonary arteries was not demonstrated. When mediastinal pulmonary arteries were not visualized, intraparenchymal pulmonary arteries were always demonstrated with extension from the hilum of the lung. At the hilum, there was considerable variation in the size of the vessels

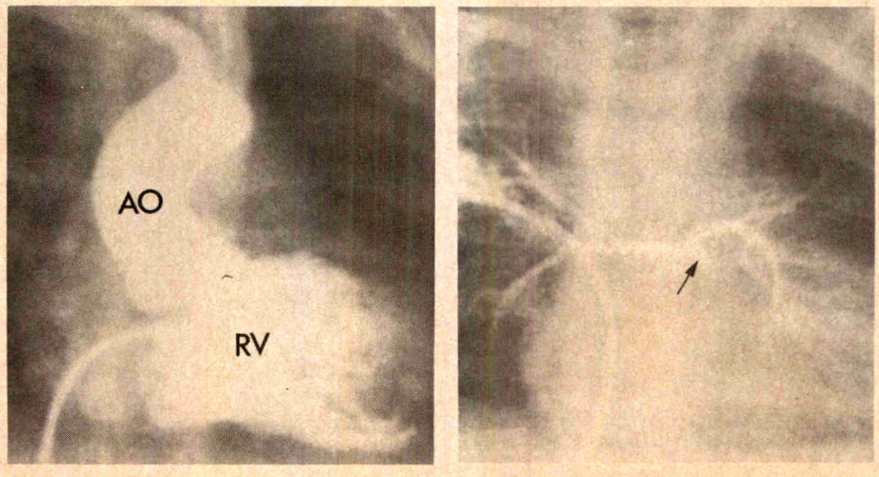

FIGURE 2. Pulmonary atresia with ventricular septal defect with confluent pulmonary arteries demonstrable only by pulmonary vein wedge angiography. **Left panel,** frontal right ventriculogram (RV) demonstrates no evidence of infundibular septation, and there is dense opacification of the ascending aorta (AO). **Right panel,** very small (2.0 mm) confluent pulmonary arteries (**arrow**) are demonstrated by pulmonary vein wedge angiography.

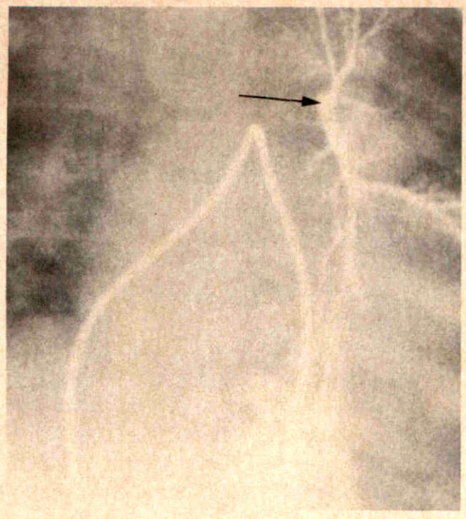

FIGURE 3. Prohibitively small hilar pulmonary artery (**arrow**) demonstrated by left pulmonary vein wedge angiography in a child with pulmonary atresia and ventricular septal defect.

(Fig. 3 to 5). From the angiographic appearance of the hilar origin of the intraparenchymal pulmonary artery, it was difficult to define with certainty the surgical accessibility. Some hilar vessels appeared to be only 2 to 3 mm in diameter (Fig. 3) while others appeared almost aneurysmal (Fig. 4). The hilar pulmonary artery (extension and confluence of intraparenchymal branches) ranged from about 2 to 15 mm in diameter.

Twelve of these 15 patients underwent heart surgery. Of the 2 with demonstrable confluence of pulmonary arteries, 1 underwent a Pott's anastomosis and the other, a right ventricular outflow tract reconstruction utilizing pericardium and leaving the ventricular septal defect open.

Ten patients with nonconfluent pulmonary arteries underwent the following surgical procedures: a Blalock-Taussig anastomosis in 7 patients (3 with Gore-tex®); right ventricular outflow tract-pulmonary artery reconstruction in 3 patients (pericardium in 2, #22 Carpentier-Edwards valved conduit in 1). Two of these 3 patients also underwent closure of their ventricular septal defects. No surgical death was encountered in these 12 patients. After the initial operation (a right Blalock-Taussig shunt), 1 patient underwent a left-sided pulmonary vein wedge injection, and a prohibitively small hilar vessel was demonstrated.

Pulmonary vein wedge angiography failed to demonstrate a confluence of mediastinal pulmonary arteries in only 1 patient where confluence (2.0 mm) was found at surgical exploration. The study had been performed early in our experience with this technique, and in retrospect, significant flushing of saline solution had not been done.

Group 2: Six patients have been identified in whom 1 pulmonary artery has been completely occluded. In 5, this was the result of a systemic-to-pulmonary artery anastomosis and in 1, a complication of a right ventricular outflow tract reconstruction. At the time of pulmonary vein wedge angiography, these patients ranged in age from 1.3 to 11.5 years. The diagnosis included the following: 1 patient with corrected transposition of the great arteries, ventricular septal defect, and pulmonary stenosis; 1 with double-outlet right ventricle, hypoplastic left ventricle, acquired pulmonary atresia, infundibular ventricular septal defect, and straddling mitral valve; 3 with severe tetralogy of Fallot or pulmonary atresia with a ventricular septal defect;

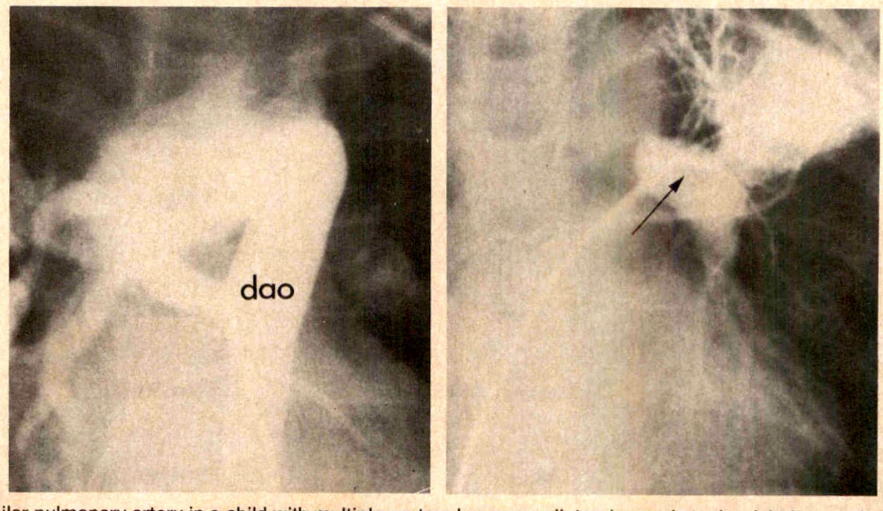

FIGURE 4. Large left hilar pulmonary artery in a child with multiple aortopulmonary collateral vessels to the right lung and presumed distal ductal (ligamental) origin of the left pulmonary artery. **Left panel,** frontal injection in descending thoracic aorta (dao) shows multiple collateral vessels to the right lung and almost none to the left lung. **Right panel,** left upper pulmonary vein wedge injection shows a hilar left pulmonary artery of about 13 mm in diameter (surgically confirmed).

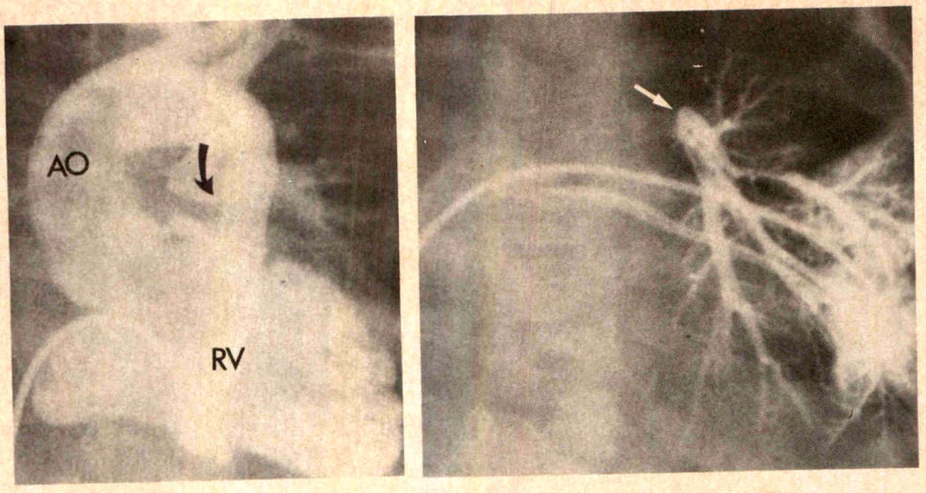

FIGURE 5. Nonconfluent pulmonary arteries originating from bilateral homologous ductus arteriosus in a patient with pulmonary atresia, ventricular septal defect, and evidence of infundibular septation. **Left panel,** the left pulmonary artery fills by way of a left ductus arteriosus (**black arrow**). **Right panel,** some months later, no opacification of the left pulmonary artery was seen from the aortogram, but a reasonable hilar left pulmonary artery (**white arrow**) was demonstrated by pulmonary vein wedge angiography.

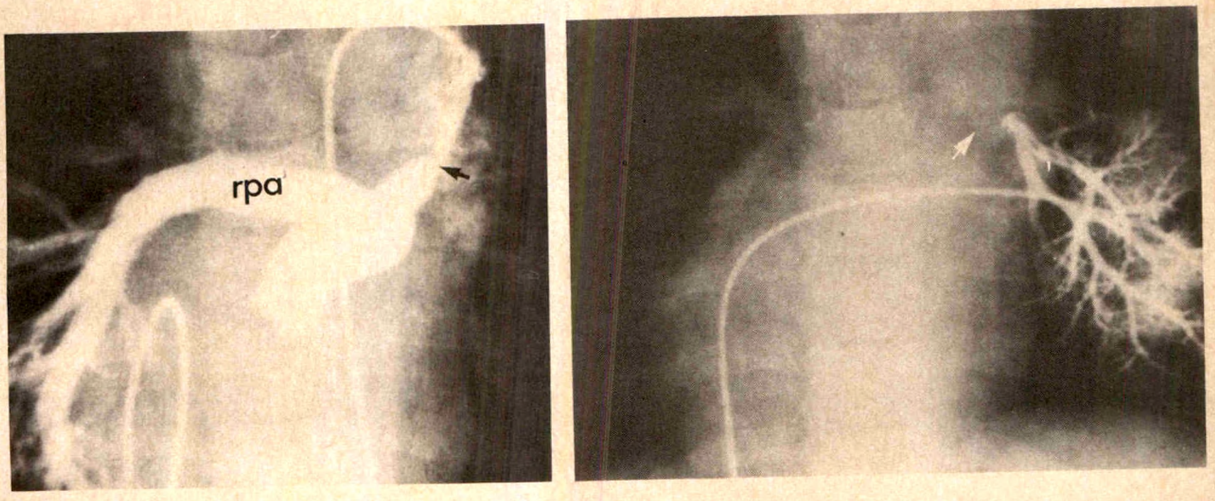

FIGURE 6. Occlusion of the left pulmonary artery by a left-sided Blalock-Taussig shunt in a patient with dextrocardia, atrioventricular discordance, single-outlet aorta, and pulmonary atresia. **Left panel,** frontal selective injection in the left-sided shunt demonstrates the caliber of the right (rpa) and main pulmonary arteries, but the left pulmonary artery distal to the shunt (**black arrow**) does not opacify. **Right panel,** a left pulmonary vein wedge angiogram demonstrates a patent but small (3.0 mm) pulmonary artery that extends to the level of the left mainstem bronchus (**white arrow**) (surgically confirmed).

and 1 patient with tricuspid atresia, restrictive ventricular septal defect, and severe pulmonary stenosis. The left pulmonary artery was the affected pulmonary artery in 5, and the right in 1 patient. The procedures responsible for complete occlusion of the left pulmonary artery included: Waterston anastomosis in 2, left Blalock-Taussig in 2, and right ventricular outflow tract reconstruction in 1. A Waterston anastomosis was responsible for complete occlusion of the right pulmonary artery in 1 patient. Left pulmonary vein wedge angiography demonstrated patency of the affected pulmonary artery distal to the occluding shunt or outflow tract reconstruction in these 5 patients, and the pulmonary artery was patent back to the level of the occluding shunt (Fig. 6). An intrapericardial right pulmonary artery was not identified by this technique. In the 1 patient whose right pulmonary artery had been obliterated by a Waterston anastomosis, only a small hilar vessel was identified.

The distal left pulmonary artery ranged from about 2 to 6 mm in diameter when visualized by pulmonary vein wedge angiography; these calibers were confirmed at the time of surgery. One patient underwent a central shunt with Gore-Tex and reconstruction of the left

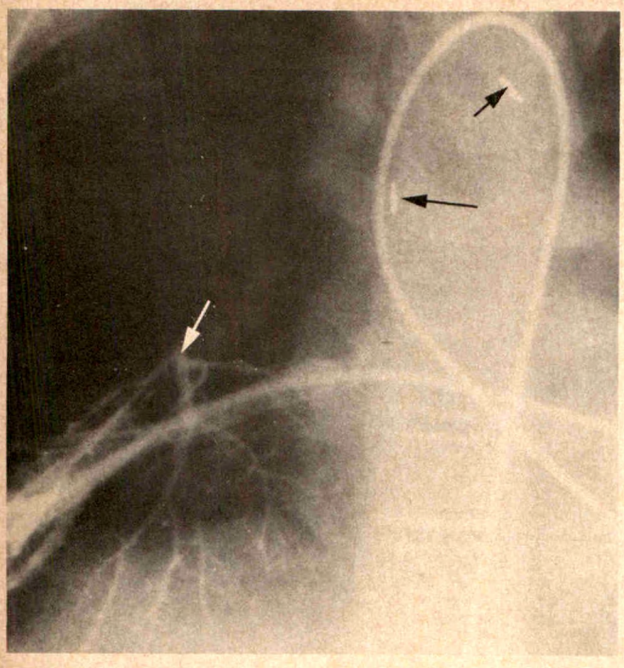

FIGURE 7. Occlusion of the distal right pulmonary artery by a right pulmonary artery band in a patient with truncus arteriosus, type 1, and bilateral pulmonary artery bands. Frontal pulmonary vein wedge injection shows a small intraparenchymal right pulmonary artery (**white arrow**). The right and left opaque pulmonary artery bands are noted (**black arrows**). See text for operative findings.

pulmonary artery. Two other patients underwent a left Blalock-Taussig anastomosis. One patient with severe tetralogy underwent a right ventricular outflow tract reconstruction with pericardium. The patch extended across the occluded origin of the left pulmonary artery. Three of the 4 patients were significantly improved by surgery.

Group 3: Pulmonary arterial banding resulted in complete occlusion (or at least nonvisualization) of the right pulmonary artery (Fig. 7) in 2 patients. One patient had had a bilateral pulmonary artery banding for a type I truncus arteriosus; the other had tricuspid atresia and transposition of the great arteries. Pulmonary vein wedge angiography was performed to determine the status of the pulmonary artery distal to the occluding band. In the patient with truncus arteriosus, pulmonary vein wedge angiography was performed by the retrograde arterial approach (Fig. 7). A mediastinal right pulmonary artery was not visualized (Fig. 7). At surgical exploration, the right pulmonary artery distal to the band was incompletely occluded with adherent thrombus extending from the level of the band to the hilum of the right lung. The pulmonary artery distal to the occluding band was shown to be patent in the second patient, but the vessel was very small. A right Blalock-Taussig anastomosis was subsequently performed.

Group 4: Two patients with so-called isolated unilateral congenital absence of a pulmonary artery have undergone pulmonary vein wedge angiography (Fig. 8). One also had a small, membranous ventricular septal defect and obstructing right ventricular anomalous muscle bundles. Pulmonary vein wedge angiography was performed in order to exclude a mediastinal pulmonary artery extending from the hilum of the affected lung to the main pulmonary artery but with atresia at its point of origin. One of these 2 patients was 3 months of age at the time of the pulmonary vein wedge injection, and the other was 4 months old. In neither was a mediastinal pulmonary artery visible (Fig. 8) and surgical exploration was not undertaken in either case.

Complications of pulmonary vein wedge angiography: Significant pulmonary complications of this technique have been uncommon.[20–22] Intrabronchial extravasation of contrast material was noted in 4 cases. One of these patients, studied early in our experience

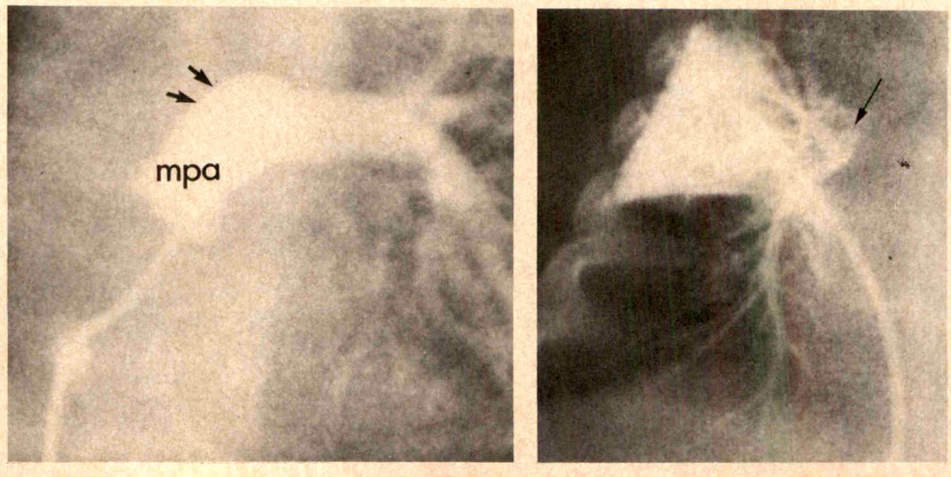

FIGURE 8. Isolated congenital absence of right pulmonary artery in a 3-month-old infant. **Left panel,** frontal main pulmonary artery (mpa) angiogram shows no filling of the proximal right pulmonary artery (**arrows**). **Right panel,** right pulmonary vein wedge angiogram shows only a small extrapericardial hilar pulmonary artery (3.0 mm). The patient did not undergo exploration.

with the technique and previously reported from this hospital, developed significant bronchospasm.[20] In the others, the extravasation produced coughing and expectoration but was well tolerated. No permanent residue was observed.

Discussion

Pulmonary vein wedge angiography has proven a relatively safe and helpful technique in our experience. Although we have extended the indications for the application of this technique, the most common indication remains the determination of the presence or absence of central pulmonary arteries in patients with pulmonary atresia, and when present, whether or not a confluence exists.

Is pulmonary vein wedge angiography really necessary when standard anterograde injections of contrast material (including selective injections of the important aortopulmonary collateral vessels) fail to visualize the central (intrapericardial or mediastinal) pulmonary arteries? In our opinion, it is. The demonstration of confluent pulmonary arteries by this technique allows a surgical alternative not permitted when a confluence does not exist. Thus, if a confluence is imaged, there is the surgical potential for connecting the right ventricle to the confluence, hopefully promoting symmetrical pulmonary blood flow and, ultimately, growth. On the other hand, if small hilar vessels only are visualized, we would still recommend surgical exploration and, when possible, construction of a systemic-pulmonary artery anastomosis into the hilum of the lung.

It must be remembered that if a lung is present, then too, the intraparenchymal pulmonary arteries are present; this is true despite the presence of pulmonary atresia. The intraparenchymal pulmonary arteries and the right and left pulmonary arteries have a different embryogenesis. For any given segment of lung in a patient with pulmonary atresia, one must determine the following: (1) How many segments of each lung connect to a true central pulmonary artery (when present)?[23] (2) Do the various segmental parenchymal pulmonary arteries interconnect? (3) What is the nature of the aortopulmonary collateral circulation, and, for any given intrapulmonary segment, what is its collateral anastomosis?[24,25] (4) Is the segment of lung protected from pulmonary vascular disease by virtue of obstruction in the aortopulmonary collateral, or at the site of connection between the aortopulmonary collateral and the parenchymal pulmonary artery?[24,26,27] Pulmonary vein wedge angiography may help resolve some of these issues, but this technique must be combined with thoughtful hemodynamic and angiographic analysis of the aortopulmonary collateral circulation.

Familial Congenital Heart Disease: How Are The Various Types Related?

PIERRE CORONE, MD, CATHERINE BONAITI, MD, JOSUÉ FEINGOLD, MD, SYLVIE FROMONT, MD, and DOMINIQUE BERTHET-BONDET, MD

The distribution of congenital heart lesions was studied in 238 families with at least 2 affected members. A statistical analysis was performed. Concordant lesions were found in 48% of the affected first degree relatives and in 28% of the affected second and third degree relatives. The concordance rate is highly significant for all lesions studied in the first degree relatives, with the exception of ventricular septal defect (VSD). Among the discordant pairs of lesions, some occur significantly more often than expected (tetralogy of Fallot associated with VSD, pulmonary stenosis, and transposition of the great arteries); others, such as the association between VSD and pulmonary stenosis, are significantly less common than would be expected on a random hypothesis. An explanation is proposed suggesting that malformations anatomically dissimilar but resulting from the same heart segment disorder may have some common genes, and that interaction between genes may be responsible for "antagonism" between 2 defects. The embryologic segmental approach to congenital heart disease is reinforced by this genetic study.

The incidence of congenital heart disease is higher in families with an affected member than in the general population.[1] The aim of this study is to analyze the relation between various types of congenital heart disease observed in families with at least 2 affected members.

Methods

A total of 238 families were studied; 202 had 2 affected members and 36 had more than 2. Ten of the probands were twins, 4 sets of which were certainly monozygous. Of the probands 108 were male and 130 female. The source of the family records is listed in Table I. Cases with doubtful diagnosis and cardiopathy linked to a chromosomal abnormality, known mendelian heredity, or environmental factors were excluded.

The pairs of cardiac defects observed in each family were defined as *concordant* when the 2 affected members have the same defect and *discordant* when the lesions are dissimilar. When a patient has more than 1 cardiac lesion, only what appeared to be the major lesion was considered (major lesion approach of Fraser and Hunter[2]).

Analysis of the concordance rate: For each malformation, the number of observed concordant pairs was compared with the number expected by chance. If x is taken as the frequency of this malformation among all cardiac malformations and n the number of pairs in the sample, the expected number of concordant pairs is nx^2.

Distribution of types of malformation in discordant pairs: The number of each of these pairs was compared with the number expected if this association were due only to chance. If x and y are the respective relative frequencies of malformations X and Y and m the number of analyzed pairs, the expected number of pairs "X-Y" is $mxy/\Sigma xy$. The value of the relative frequency of various types of cardiac defects was taken from Keith et al.[3]

Interpretation of test results: Because in these 2 tests the expected numbers were usually low, binomial distribution was used. Tests were always bilateral. Keeping in mind the great

number of comparisons, we suggest that tests be interpreted as follows: $p > 0.05$ = not significant (NS); $0.01 < p < 0.05$ = doubtful; $0.001 < p < 0.01$ = significance is likely but needs confirmation by further studies; $p < 0.001$ = highly significant.

Results

Table II indicates the distribution of the pairs of affected members according to degree of the relationship and the kind of defect. The overall concordance rate is 48% for first degree relatives and 28% for second and third degree relatives. Among the 4 monozygous twins, 3 had corcordant lesions.

Statistical analysis concerns the 8 most frequent malformations in first degree relatives (47 concern parent-child pairs and 131 sibspairs). Concordance rates are presented in Table III and the distribution of discordant pairs in Table IV. In each of these tables, we pooled our data with those from other reports: Furhmann[4] and Sanchez-Cascos[5] for concordant pairs (Table III), Furhmann[4] and Fraser and Hunter[2] for discordant pairs (Table IV). The absence of heterogeneity in the distribution of pairs between samples was previously tested.

For each malformation studied, the concordance rates were highly significant, except with VSD, at least in terms of the pooled data (Table III, last column). The distribution of discordant pairs shows some associations to be significantly more frequent than expected (positive associations) and others significantly less frequent than expected (negative associations) (Table IV).

Discussion

Concordant pairs: Our data show that in the majority of congenital heart defects, 2 relatives are more often affected by the same defect than would be expected by chance alone. This finding suggests that congenital heart diseases are not a homogeneous entity, but rather that each kind of defect must be considered

as specific and related to a particular mechanism. As for ventricular septal defect (VSD), the low rate of concordance may result from the heterogeneity of this malformation. In this way, genetic data agree with embryologic data which show that VSD may result from abnormalities of different segments of the primitive heart tube: atrioventricular canal, primitive ventricle, or conus.[6]

Positive association among discordant pairs: Tetralogy of Fallot, transposition of the great arteries, and VSD make up a definite "cluster" in our study as in those of others.[2,4,5,6] As these malformations are all consequences of conotruncal abnormalities,[7] some common genes may be considered responsible for the various lesions of the same heart tube segment: the conotruncus. This view fits in with the "segmental approach" recommended by Van Praagh and Van Praagh,[8] and also with the elegant observations of Van Mierop et al[9] in Keeshond dogs. Mating Keeshond dogs with hereditary defects of conotruncal septum, they obtained abnormal embryo hearts with a large spectrum of conotruncal malformations such as VSD, tetralogy of Fallot, truncus arteriosus, and dextroposition of aorta.

In other words, some families appear to possess a conotruncal susceptibility. Defects as different as tetralogy of Fallot, transposition of the great arteries, and VSD may be considered simple subgroups of a basic conotruncal anomaly. It is a first step towards an embryologic concept of congenital heart disease.

Negative associations among discordant pairs: A statistical bias may account for doubtfully significant ($p < 0.05$) negative associations, because relative frequency has been used. However, when significance is high, another explanation should be sought. We suggest that interaction between effects of genes at different loci ("epistasis") is one hypothesis that may account for some of these unexpected observations.

Let us consider in particular the low frequency of pairs of "ventricular septal defect-valvular pulmonary stenosis," which is very surprising in view of the fact that these 2 lesions are so often associated in the same patient within the framework of tetralogy of Fallot. Assuming multifactorial inheritance,[10] we suggest that genes responsible for pulmonary stenosis may favor the expression of genes responsible for VSD and vice versa, the existence of the 2 types of genes in an individual being responsible for tetralogy of Fallot.

TABLE IV Familial Associations Between Discordant Congenital Heart Disease in First Degree Relatives

Abbreviations as in Table II.

If patient A is affected by isolated pulmonary stenosis, he must have very few VSD genes, otherwise he would have manifested tetralogy of Fallot. Let us consider patient B, who is closely related to A and therefore has a somewhat similar genetic constitution. If he is to be affected, he is likely to have pulmonary stenosis, or if by chance he has more VSD genes than patient A, he would have tetralogy of Fallot but not an isolated VSD.

This hypothesis, which is possibly too schematic and requires confirmation, is compatible with data concerning the observed association between types of malformation in affected relatives: high concordance rates for a given type, positive associations between 2 types having some common genes, negative associations between 2 types due to genes with epistasis effects. However, other models could explain these phenomena as well. In addition, the data are too few to permit a valuable test for any model at the present time.

Conclusion: A statistical analysis of the pairs of congenital heart lesions observed in families with at

least 2 affected members demonstrates nonrandom distribution. In addition to the concordant lesions observed in roughly 50% of cases for first degree relatives, the analysis of discordant lesions shows (1) excess in some pairs, highlighting "clusters" of lesions and suggesting that these lesions, although dissimilar, have some common genetic origin, and (2) deficits in some pairs, which may be a consequence of interaction between effects of genes. This leads us to think of the heart not as a genetic whole but rather as being constituted of different specific genetically determined segments. This concept agrees with the embryologic "segmental approach" suggested by Van Praagh and Van Praagh.[8]

Acknowledgment: We thank our colleagues who supplied us with the data that made this study possible and Samuel Berenberg, MD, for reviewing the manuscript.

Left Ventricular Wall Stress in Compensated Aortic Stenosis in Children

RICHARD DONNER, MD, BLASE A. CARABELLO, MD, IAIN BLACK, MD, and JAMES F. SPANN, MD

It is known that children with aortic stenosis (AS) frequently have supernormal indexes of left ventricular (LV) pump function and remain compensated for many years. Factors causing this increase in pump performance have not been elucidated. A study was done on LV mechanics in 11 children with AS (aortic valve area 0.5 ± 0.3 cm^2/m^2) and 10 normal subjects. The ejection fraction in the AS group (0.88 ± 0.08) was significantly higher than in normal subjects (0.64 ± 0.08, $p < 0.001$). The mean velocity of fiber shortening was also higher in AS patients (1.80 ± 0.35 circ/s) than in normal subjects (1.22 ± 0.21 circ/s, $p < 0.001$). The end-systolic volume index in patients with AS (9 ± 8 ml/m^2) was much lower than in normal subjects (27 ± 8 ml/m^2). LV mass in patients with AS was 180 ± 58 g/m^2 compared with 96 ± 9 in normal subjects. LV wall stress was reduced throughout the cardiac cycle in patients with AS. Peak stress in patients with AS was 238 ± 51 dynes/$cm^2 \cdot 10^3$ versus 439 ± 85 in normal subjects. The end-systolic stress–end-systolic volume index ratio, an indicator of contractile state, was not elevated in patients with AS. It is suggested that diminished wall stress in concert with normal contractile function permits the supernormal pump function seen at rest in children with AS.

The performance of the pressure-overloaded heart, a subject of recent controversy, has been described by the intrinsic function of the contractile mechanism and by its pump function as assessed by ejection indexes. It is clear that hypertrophy and other compensations maintain pump function in the initial stages of pressure overload, but if overload is excessive and prolonged, pump function eventually fails. Recent animal[1–16] and human[17–27] studies show that contractile muscle function varies from normal in some pressure-overloaded hearts to depressed in others. Some studies in animals have even shown supernormal pump function[10] and have suggested increased contractile muscle function[23] in experimental pressure overload. It is recognized that children with aortic stenosis (AS) have supernormal pump function and remain compensated for many years.[28–30] We wanted to know what specific changes in ventricular mechanics or cardiac muscle characteristics permit this supernormal pump performance and how this information is related to what is known about ventricular mechanics and muscle function in other forms of pressure overload. Therefore, we assessed left ventricular (LV) ejection indexes, loading conditions, wall stress, and contractile muscle function in children with AS.

Methods

Patient groups: Two patient groups were established: 11 patients with AS (mean age 10 ± 3.6 years, mean body surface area 1.12 ± 0.33 m^2) and 10 normal patients (mean age 8.5 ± 2.9 years, mean body surface area 1.15 ± 0.24 m^2). All were studied by cardiac catheterization.

Eight patients with AS had valvular obstruction; 1 had a subvalvular membrane and 2 had supravalvular obstruction. All were asymptomatic with no previous history of chest pain, heart failure, syncope, associated cardiac lesions, or cardiac surgery. Aortic regurgitation was excluded by aortic root angiography.

The normal patients were all asymptomatic and underwent cardiac catheterization to exclude significant heart disease suggested by physical examination and noninvasive testing. All proved free of cardiac disease.

Catheterization and ventricular performance analysis: Catheterization was performed from the femoral vessels under light sedation with a mixture of meperidine, promethazine, and chlorpromazine. The aortic valve was crossed by the retrograde approach; because the smaller femoral artery diameter in children may be associated with vascular compli-

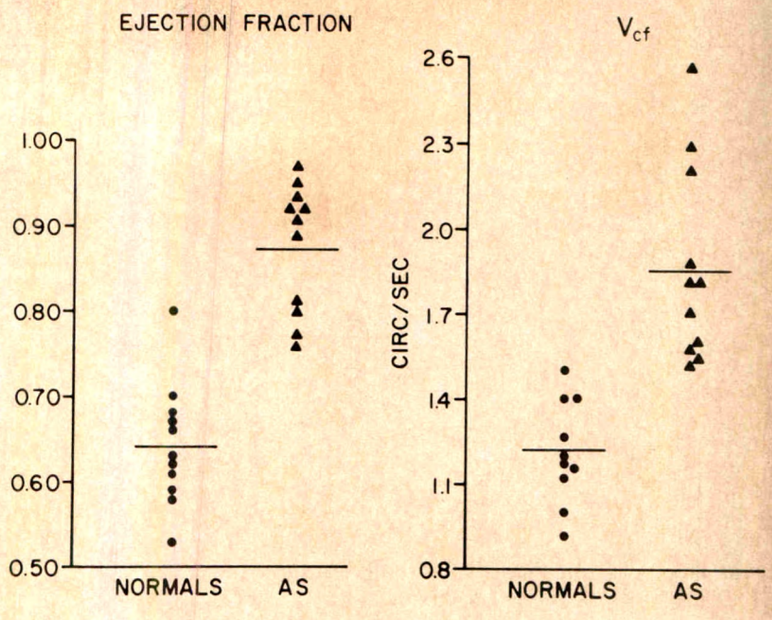

FIGURE 1. Ejection fraction and Vcf for normal subjects (**circles**) and patients with AS (**triangles**) shown. Both are significantly increased in aortic stenosis. The **horizontal line** represents the mean value for each patient group.

cations, a second arterial catheter to provide simultaneous LV and aortic pressures was not employed. Pressure tracings were obtained from the left ventricle and ascending aorta by a fluid-filled catheter system and recorded at 75 or 100 mm/s with a simultaneous electrocardiogram. The LV pressure was obtained just before angiography. To determine the time difference between a micromanometer-tipped system and fluid-filled catheters, we measured pressures simultaneously with both catheters in 17 randomly chosen cardiac cycles in 2 dogs. The time delay in peak LV pressure from micromanometer to fluid-filled catheters was 13.2 ± 3.1 ms, a delay of <1 cineangiographic frame. Because this does not significantly alter the relation of pressure to volume, especially at end systole, no time-lag correction was used.[17,31] The transvalvular gradient was obtained by planimetering superimposed aortic and LV pressure traces recorded sequentially before angiography. A mean cardiac output was calculated from Fick determinations obtained early in the course of the catheterization; heart rate during Fick determinations and pressure-volume analysis agreed within 11 beats/min in all cases and 7 beats/min in most cases. The aortic valve area was estimated from the Gorlin formula and indexed by body surface area.[32]

Single-plane LV angiograms were performed in the anteroposterior projection (9 patients) and right anterior oblique projection (2 patients) filmed at 60 frames/s. LV volumes were calculated utilizing a digitizer, the area-length method, and regression equations for the respective projections.[33,34] Volumes were indexed by body surface area. End-diastolic volume was defined as the largest volume measured in a cardiac cycle. End-systolic volume was measured at the time of aortic valve closure, which corresponded to the smallest volume in every case. Wall thickness was measured at end-diastole at midcavity level. Because we recognized the practical and theoretical difficulties of measuring small end-systolic volumes accurately, we determined intra- and interobserver variation and compared our angiographic end-systolic volumes with those calculated from the end-diastolic volume, Fick cardiac output, and heart rate. Maximal intraobserver variation was 5 ml at end-diastole and 2 ml at end-systole. Maximal interobserver variation was 7 ml at end-diastole and 5 ml at end-systole. The mean end-systolic volumes calculated by angiographic and Fick methods were nearly identical ($Y = 1.1 X + 0.2$, $r = 0.93$). Ejection fraction was calculated in the usual manner. The mean velocity of circumferential fiber shortening (Vcf) was obtained using the formula $Vcf = (EDD - ESD)/(EDD \cdot ET)$, where EDD is the end-diastolic minor axis, ESD is the end-systolic minor axis, and ET is the ejection time measured from the upstroke of the aortic pressure trace to the dicrotic notch. LV mass was calculated by the method of

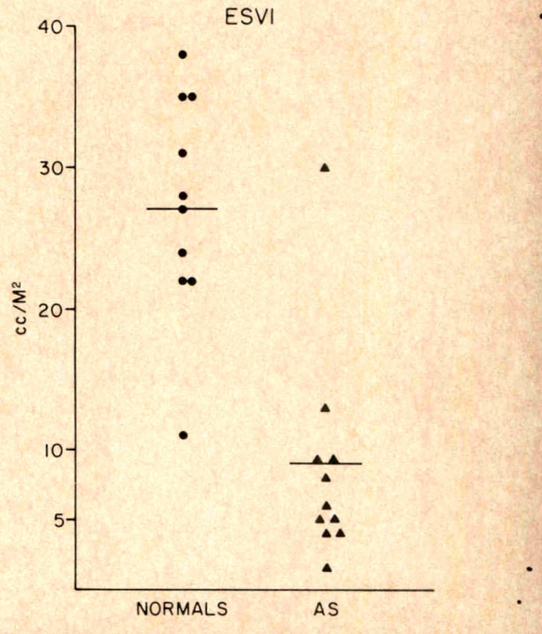

FIGURE 2. End-systolic volume index is much lower in patients with AS (**triangles**) than in normal subjects (**circles**). The **horizontal line** represents the mean value for each patient group. ESVI = end-systolic volume index.

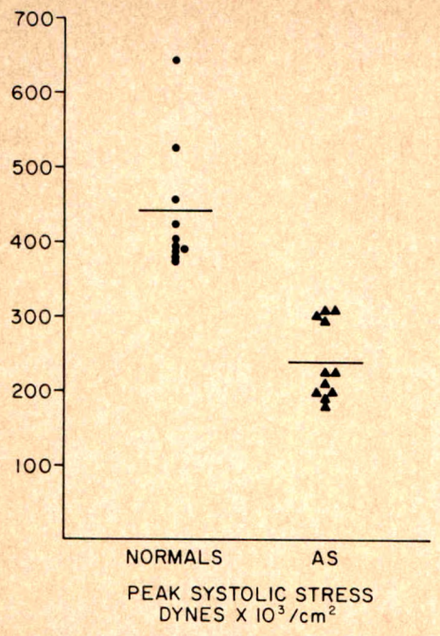

FIGURE 3. Peak wall stress in patients with AS (**triangles**) is significantly lower than that in normal subjects (**circles**). The **horizontal line** represents the mean value for each patient group.

Kennedy et al.[33] Stroke work index was calculated using the formula stroke work index = mean LV pressure × stroke volume index × 0.0136 g·m/mm Hg, where mean LV pressure is obtained from the sum of the mean aortic pressure and transvalvular gradient and the stroke volume index was obtained angiographically.

The cycle length of aortic and LV pressure traces and angiographic beats were then examined, and beats with a common cycle length were selected. Extra- and postextrasystolic beats were excluded. In no instance did pressure or angiographic cycle lengths differ by more than 10 ms. A frame-by-frame analysis of ventricular wall stress was performed for the entire cardiac cycle using the Hugenholtz[35] approximation for wall thickness during systole, the formula of Mirsky[36] and the computer-assisted method of Gunther and Grossman.[27] End-systolic stress was taken at end-systole as previously defined and peak stress was defined as the maximal stress present in the cardiac cycle. Mean systolic stress was calculated by obtaining the area under the stress-time curve between end-diastole and end-systole and dividing by this time interval. The use of mean systolic stress further minimizes the error introduced into the time course of stress development as measured by fluid-filled catheters.[27]

To validate our methods further, we studied 2 patients with AS utilizing a micromanometer-tipped catheter in the left ventricle and simultaneous pressure-volume data obtained by examining the levophase of a main pulmonary artery angiogram.[28]

Data from normal subjects were analyzed in an identical fashion.

Statistical analysis: All values were expressed as mean ± 1 standard deviation. Measured and calculated results for the AS and normal groups were evaluated using an unpaired t test. Linear regression was performed by the method of least squares.

Results

Hemodynamic data: The mean LV to aortic peak gradient was 109 ± 43 mm Hg and the mean calculated aortic valve area was 0.5 ± 0.3 cm^2/m^2. There was no significant difference between the heart rates in the AS (103 ± 23 beats/min) and normal groups (100 ± 26 beats/min).

Pump function: The cardiac index was similar in the 2 patient groups (4.7 ± 1.8 liters/min/m^2 in the patients with AS, 5.2 ± 1.6 in the normal subjects). Figure 1 shows that the ejection fraction and mean Vcf were significantly higher in the AS patients (0.88 ± 0.08, 1.80 ± 0.35 circ/s) than in the normal subjects (0.64 ± 0.08, 1.22 ± 0.21, $p < 0.001$). The stroke work index was also

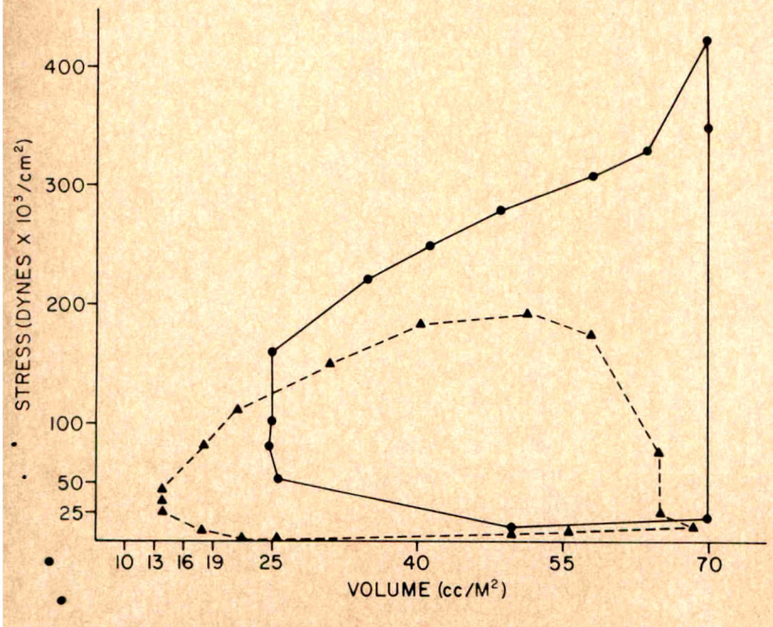

FIGURE 4. Frame-by-frame values for wall stress are plotted against the left ventricular volume index for a normal subject (**circles**) and a patient with AS (**triangles**) who had similar end-diastolic volumes. Note that throughout the cardiac cycle, wall stress was lower in the patient with AS. End-systolic volume was also reduced in the patient with AS.

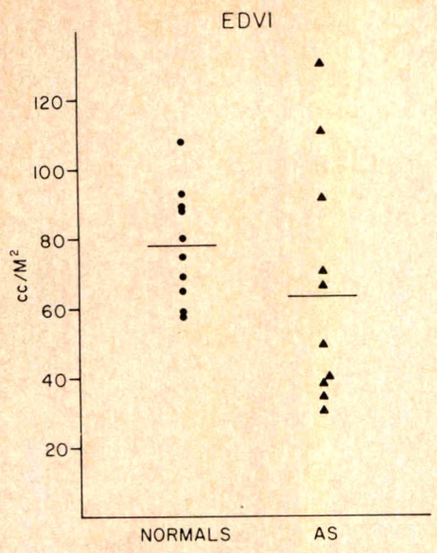

FIGURE 5. End-diastolic volume index (EDVI) for patients with AS (**triangles**) and normal subjects (**circles**). A wide overlap is demonstrated. The **horizontal line** represents the mean value for each patient group.

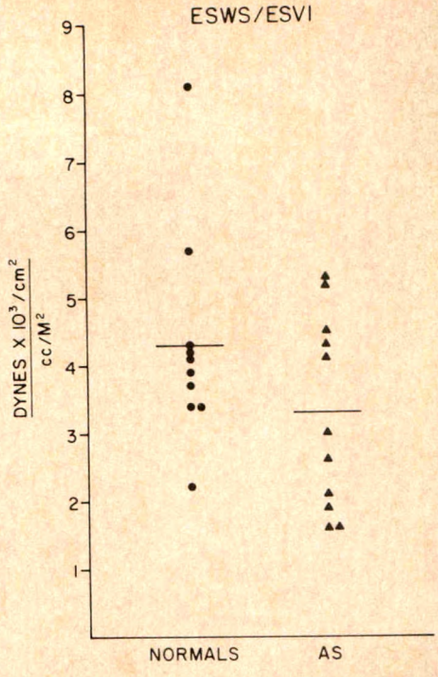

FIGURE 6. The end-systolic wall stress–end-systolic volume index ratio for patients with AS (**triangles**) and normal subjects (**circles**). There is no significant difference. The **horizontal line** represents the mean value for each patient group. ESVI = end-systolic volume index; ESWS = end-systolic wall stress.

higher in the AS patients (91 ± 49 g·m/m^2) than in the normal subjects (50 ± 12 g·m/m^2, p = 0.02).

Ventricular mechanics: In an effort to explain the increased pump performance, we examined LV pressure, wall thickness, muscle mass, volume, wall stress, and contractile indexes.

LV peak systolic pressure in the AS group (193 ± 46 mm Hg) was significantly higher than the value in normal subjects (105 ± 11 mm Hg, p <0.001). End-diastolic pressure was within the normal range in all patients.

There was extensive hypertrophy in the AS group. LV mass index was significantly increased in the AS group (180 ± 58 g/m^2) compared with normal subjects (96 ± 9, p <0.001). Wall thickness was similarly doubled in the AS group (1.13 ± 0.26 cm) compared with that in the normal patients (0.51 ± 0.1, p <0.001).

The end-systolic volume index was much lower in the AS group (9 ± 8 ml/m^2), averaging one third of the normal value (27 ± 8, p <0.001) (Fig. 2).

Peak systolic stress was strikingly reduced in the AS group (238 ± 51 dynes/cm^2·10^3), averaging approximately half the normal value (439 ± 85, p <0.001) (Fig. 3). End-systolic stress in the AS group (24 ± 12 dynes/cm^2·10^3) was less than one fourth the normal value (109 ± 30, p <0.001). Mean systolic stress was also lower in the AS group (126 ± 26 dynes/cm^2·10^3) than the normal group (327 ± 58, p <0.001). Systolic stress was reduced at all points throughout systole as demonstrated in the stress-volume loops of Figure 4.

The end-diastolic volume index was slightly lower in the AS group but varied widely from patient to patient and overlapped in the 2 groups (Fig. 5).

The ratio of LV wall stress to LV volume index at end-systole was used as an estimate of LV contractile muscle function. There was substantial overlap in the individual values for the ratio of end-systolic wall stress to end-systolic volume index in the 2 groups of patients, as shown in Figure 6. None of the values for this ratio in the AS patients were higher than the highest value in the normal group.

Results obtained in 2 patients with AS utilizing micromanometer-tipped catheters and simultaneous pressure-volume data were consistent with the findings in the AS group. The respective LV to aortic gradients were 99 and 81 mm Hg, end-diastolic volume indexes 49 and 68 ml/m^2, end-systolic volume indexes 5 and 13 ml/m^2, ejection fractions 0.90 and 0.81%, and Vcfs 1.65 and 1.57 circ/s. Peak systolic stresses were 229 and 212 dynes/cm^2·10^3, end-systolic stresses were 48 and 36 dynes/cm^2·10^3, and the ratios of end-systolic stress to end-systolic volume index were 9.6 and 2.8, respectively.

Discussion

An important finding of this study is that LV wall stress in children with AS is lower than normal throughout systole. This occurs despite much higher systolic pressures in AS patients. Previous studies in adults with compensated pressure overload have shown that wall thickness increases, offsets the pressure overload, and maintains normal wall stress.[37,38] However, in our children with AS, increases in wall thickness appear to have provided overcompensation for the pressure overload.

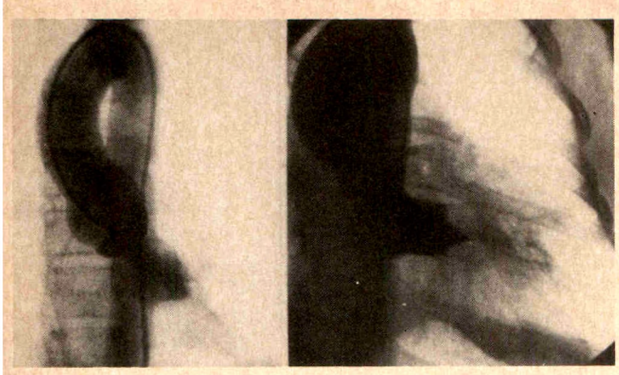

FIGURE 7. End-systolic frames from 2 patients with aortic stenosis. The end-systolic volume index in the left frame is 9 ml/m^2 and in the right frame, 3 ml/m^2.

We also found ejection fraction and Vcf were increased in these children, corroborating previous reports.[28–30] The observed subnormal wall stress, acting to reduce LV afterload, may have permitted the supernormal pump performance. This is probable since it is well known that a reduction in afterload will increase ejection fraction and Vcf while decreasing end-systolic volume.[27,39–42] Our patients with AS had a striking reduction in end-systolic volume (Fig. 7). In 9 of 11 patients, end-systolic volume index was <10 ml/m^2. While calculation of such small volumes is prone to error, the variation of end-systolic volume index needed to significantly reduce ejection fraction and increase end-systolic stress is far beyond our inter- and intraobserver error. Our very small end-systolic volumes are also corroborated by the Fick method as well as direct inspection of the end-systolic frames in Figure 7.

It is unlikely that the large increase in pump performance was provided by increased preload, since the end-diastolic volume was normal or low in the AS patients. This increased pump performance could also have resulted from a similarly large increase of contractile muscle function. This did not appear to occur since the end-systolic stress-volume ratio in AS patients overlapped extensively with that in normal subjects. The relation between afterload and volume at end-systole has been proposed as a contractile index which is thought to be relatively independent of loading conditions.[40,43–49] As shown in Figure 6, we used the ratio of end-systolic wall stress to end-systolic volume index as an estimate of contractile muscle function. We recognize the limitation of estimating contractile muscle function by this method. Although this ratio is probably less accurate than manipulating patients through a range of loading conditions to obtain the slope of the end-systolic stress-volume relation, we have found this ratio clinically useful and a valid approximation of the *true* end-systolic relation.[26,50–52] This should allow us to exclude the large increases in contractile muscle function that would be required to explain our patients' increased pump performance due to increased contractile muscle function alone.

How do the current data fit in with and add to what is known about pump and contractile muscle function in other examples of pressure-overloaded hearts? Taken together, the data of previous animal and human studies suggest a pathologic continuum from the one extreme of poorly functioning muscle in a pressure overloaded heart with impaired pump function to the other extreme of normally functioning muscle in a pressure overloaded heart with normal or even excessive pump function. At one extreme, when ventricular pressure overload is chronic and severe, heart failure occurs and contractile function is depressed.[2,4,7,8,12,13,17–21] In the middle ground, contractile and pump function may be normal or abnormal. There may be normal contractile function in an excessively overloaded heart where hypertrophy does not normalize ventricular wall stress and pump function is thereby reduced.[18,19,27] In animal and human experiments there may be moderately depressed contractile function in an adequately hypertrophied pressure-overloaded heart which has normal pump function at rest.[2,5,7,8,17,18] At the other extreme, in experimental animals when pressure overload is less severe, pump function is normal or supernormal and contractile function is usually normal.[1,3,9–11] Our data appear to fit in with the above observations at the positive extreme of the proposed pathologic continuum by showing supernormal pump function and normal contractile function, findings not previously reported in man. Unlike experimental animals, however, pressure overload in our AS patients was severe.

The significance of our findings is unclear. It may well be that although stress is subnormal at rest, it becomes normal when higher LV pressures develop during exercise and the LV has adapted to these higher loads. One can speculate that this "stress reserve" is a factor which helps maintain the prolonged period of hemodynamic compensation seen in children with AS.

Measurement of Systemic and Pulmonary Blood Flow And QP/QS Ratio Using Doppler and Two-Dimensional Echocardiography

STEPHEN P. SANDERS, MD, SCOTT YEAGER, MD, and ROBERTA G. WILLIAMS, MD

A noninvasive method for measuring systemic and pulmonary blood flow using Doppler velocimetry combined with 2-dimensional (2-D) echocardiography has been developed. High correlations were found between Fick- and Doppler-derived indexed measurements of systemic and pulmonary flow as well as the pulmonary to systemic flow ratio in 33 patients undergoing cardiac catheterization (systemic flow [n = 28], r = 0.78; pulmonary flow [n = 21], r = 0.88; Qp/Qs ratio [n = 24], r = 0.85). The random errors of the 2 methods were not significantly different. Outflow tract obstruction, semilunar valve regurgitation, and patent ductus arteriosus were the only lesions in which limitations to the use of this method were encountered. We anticipate that this method will be of use in initial and serial evaluations of adult and pediatric patients with low cardiac output or intracardiac shunts.

Pulsed Doppler velocimetry, used in conjunction with 2-D echocardiography, has received increasing attention as a tool for noninvasive measurement of blood flow. Steingart et al[1] demonstrated that the area under the aortic Doppler frequency-time curve is proportional to left ventricular stroke volume in dogs. Hoenecke et al[2] reported estimation of cardiac output using pulsed Doppler for measurement of flow velocity and angiography for measurement of vessel diameter. Bommer et al[3] and Magnin et al[4] reported estimation of cardiac output in adults using pulsed Doppler and 2-D echocardiography.

We have developed a method for measuring blood flow in both the aorta and pulmonary artery, using a relatively low transmitted frequency which enables detection of high flow velocity and increases the operating depth of the range-gated system. Furthermore, Doppler velocity measurements were facilitated by selecting transducer positions that allow the ultrasonic beam to be aligned parallel to the direction of blood flow, eliminating the need to measure the incident angle. This report describes our method for measuring systemic and pulmonary blood flow and pulmonary to systemic flow ratio (Qp/Qs) and compares its performance with simultaneous determinations of blood flow using the Fick principle.

Methods

Subjects: Thirty-three patients aged 2 weeks to 23 years (median 9 months) and weighing 2 to 83 kg (median 7) underwent measurement of systemic or pulmonary blood flow, or both, using Doppler at the time of cardiac catheterization between November 1981 and March 1982. The cardiac lesions included ventricular septal defect (13 patients), complete common atrioventricular canal (8 patients), valvular pulmonary stenosis (3 patients), valvular aortic stenosis (2 patients), atrial septal defect (2 patients), tetralogy of Fallot (1 patient), tetralogy of Fallot after repair (1 patient), anomalous origin of the left coronary artery from the pulmonary artery (1 patient), transposition of the great arteries after Senning repair (1 patient), and hepatic arteriovenous malformation (1 patient). Patient selection was based on (1) absence of significant patent ductus arteriosus, (2) stability of the patient during measurements, and (3) absence of complex anatomic or physiologic features that would make the usual Fick calculations inapplicable, such as uncorrected transposition of the great arteries.

Procedure: Each patient initially underwent echocardiographic examination using a Picker Echoview 80 CI with a mechanical sector scanner and a 5.0 or 3.5 MHz transducer (active element diameter 13 or 19 mm; focal length 5 or 9 cm)[5,6] for measurement of the diameter of the proximal ascending aorta and main pulmonary artery. Subxiphoid views

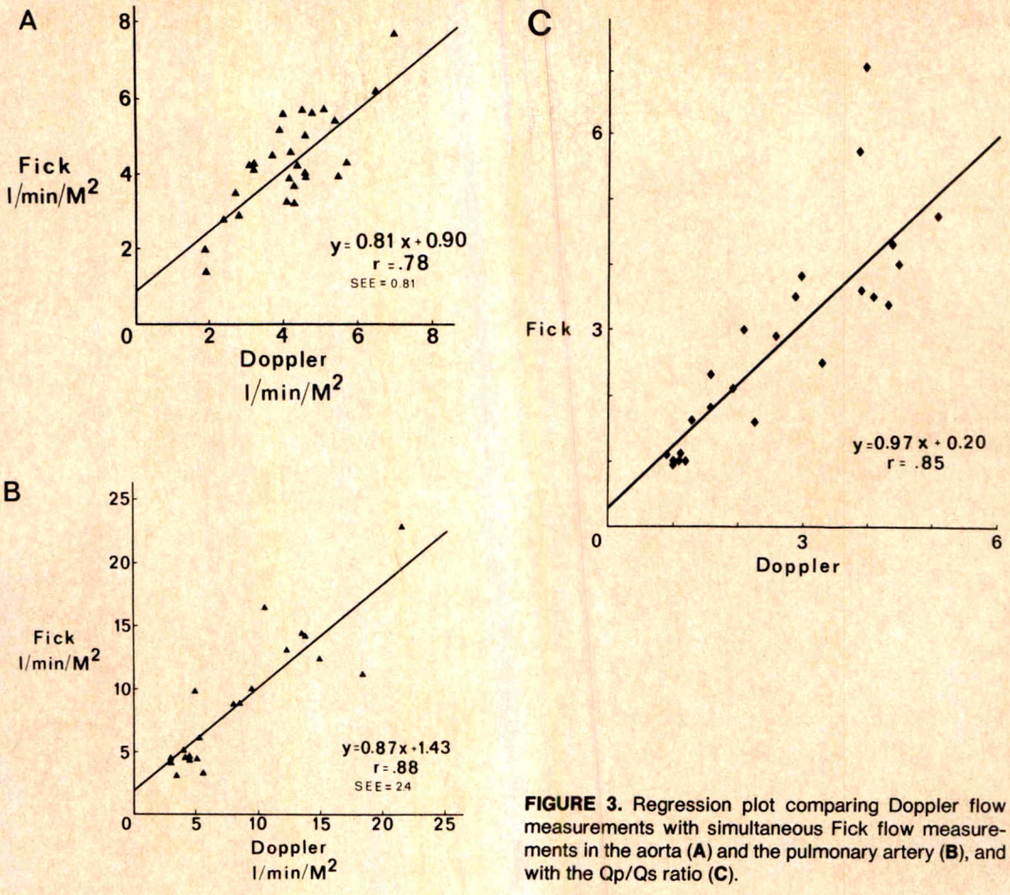

FIGURE 3. Regression plot comparing Doppler flow measurements with simultaneous Fick flow measurements in the aorta (**A**) and the pulmonary artery (**B**), and with the Qp/Qs ratio (**C**).

the random error of the Doppler method is not significantly different from the random error of the Fick method. Moreover, Doppler and 2-D echocardiography are noninvasive and easily repeatable.

Outflow tract stenosis, semilunar valve regurgitation, and patent ductus arteriosus are the only limitations to the use of this method encountered thus far. Turbulence and extremely high velocity flow due to stenotic lesions cause signal aliasing and spectral broadening. Semilunar valve regurgitation results in an overestimation of flow due to failure to measure the regurgitant volume. Our previous observations indicate that with patent ductus arteriosus, the systemic flow is overestimated and pulmonary flow underestimated because of the location of the aortopulmonary connection distal to the points of sampling in the pulmonary artery and the aorta. There was no difficulty in identifying patients with outflow tract stenosis, in whom the Doppler method was not applicable, because even relatively mild stenosis produces marked distortion of the frequency-time plot. Significant semilunar regurgitation was evident when retrograde diastolic flow was detected in the subvalvular area. However, patent ductus arteriosus may be difficult to identify in the presence of other defects and may lead to underestimation of pulmonary flow and Qp/Qs ratio.

Although previous investigators[2–4] have not done so, we have reported our results based on flow measurements indexed for body surface area. We believe that indexed volumes should be used for comparative studies because (1) indexed outputs are more meaningful and more commonly encountered clinically, and (2) comparison of unindexed outputs allows the variation in the size of the patients to "improve" the apparent correlation between invasive and noninvasive measurements.

Although measurement of blood flow in the aorta and pulmonary artery using Doppler techniques seems straightforward in principle, attempts to develop useful clinical methods have encountered numerous practical problems. These include (1) measurement of the great artery dimensions and adjustment for systolic expansion, (2) compensation for the angle between the ultrasonic beam and the direction of blood flow, (3) adjustment for differences between the peak velocity of flow measured by Doppler shift and the actual average velocity of flow as determined by the velocity profile within the vessel, (4) the conflicting requirements for pulse repetition frequency imposed by the need to measure high flow velocities at a large sampling depth, and (5) the limited availability of reliable real-time signal processing.

Vessel dimensions: We used high resolution 2-D echocardiography to obtain the maximal systolic great artery diameter and used that value to calculate the cross-sectional area of the vessel. Previous studies have shown that the cross-sectional area of the aorta increases 5 to 10% during systole, while that of the pul-

onary artery increases 2 to 18%.[10–12] The increase in ameter occurs early in systole, concomitant with the ostroke of the pressure tracing, so that most antero-ade flow in the ascending aorta or pulmonary artery curs when the vessel is at or near its peak systolic di-ension.[11]

Incident angle: We aligned the Doppler beam par-lel (within 20°) to the direction of blood flow. The oppler shift is proportional to the cosine function of e incident angle, which approximates unity for angles ss than 20° (>0.94). Under these conditions, the in-antaneous peak frequency of the Doppler signal anslates directly to the instantaneous peak velocity blood flow, as described by the Doppler equation.[1]

Velocity profile: In order to calculate blood flow, the elocity profile in the artery must be such that the peak elocity of blood flow, as represented by the envelope the Doppler frequency-time curve, is proportional to ıe mean velocity of flow and the proportionality con-ant must remain the same throughout systole. Pre-ous studies have shown that the flow profile in the scending aorta is quite flat for several centimeters ove the valve.[13] Therefore, we confined our sampling te to the immediate supravalvular area and assumed ıat the peak and mean velocities were equal through-ıt systole. This practice undoubtedly results in a slight erestimation of mean flow velocity. Again we assumed ıat conditions in the pulmonary artery were the same those in the aorta.

Pulse repetition frequency: The sampling theorem ates that for the returning Doppler-shifted signals to e faithfully reconstructed, the pulse repetition fre-ıency must be at least twice the highest frequency ıift encountered.[14] The Doppler frequency shift is rectly proportional to the velocity of blood flow, so ıat for any transmitted frequency, the minimal pulse petition frequency must increase as the velocity of ow increases. However, the maximal sampling depth inversely proportional to the pulse repetition fre-ıency because of the finite transit time of the pulsed gnal. Because the Doppler frequency shift is also di-ctly proportional to the transmitted frequency, the se of a lower transmitted frequency decreases the oppler shift produced by any given velocity of blood ow and concomitantly decreases the minimal pulse repetition frequency required for faithful reproduction of the signal. We found that a 1.5 MHz transducer is an acceptable compromise which provides adequate sampling depth on the one hand and unambiguous velocity measurements on the other.

Signal processing: The introduction of fast Fourier, transform-based spectrum analyzers has provided essentially real-time analysis and display of the Doppler quadrature output. These devices avoid the inherent inaccuracies of zero-crossing detectors, the bulk and expense of banked filters, and the inconvenience of off-line analysis. The output display of the analyzer used in this study is a frequency-time plot with amplitude displayed as shades of gray. We have found that in the absence of outflow tract obstruction, there is a well defined maximal frequency envelope that can easily and reproducibly be traced.

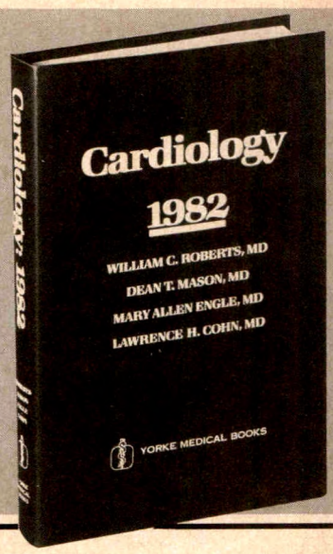
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format an style fundamental and new information essential to understanding th current thinking on managing cardiovascular disease. It coordinate what's new with well-established data, arming the reader with a pe spective on the field which is simply unavailable elsewhere. Its libera use of illustrations and original tables condenses valuable informatio into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, New York 11205 AJCC3

☐ Please send me a copy of the 1982 edition at the full price of $45.00. I do not wish to place a standing order.

☐ Enclosed is my check for _____. Yorke pays postage and handling. (Same return privilege)

(New York residents add appropriate sales tax. Add $5.00 per book for orders outside the U.S. and Canada.)

☐ Please bill my ☐ VISA ☐ MasterCard (same return privilege)

F SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
ral® (propranolol hydrochloride)

FORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN OULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC CEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

onchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and er than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary lmonary hypertension; 6) congestive heart failure (see WARNINGS) unless it is sec- ry to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic- henting psychotropic drugs (including MAO inhibitors), and during the two week lrawal period from such drugs.

WARNINGS

DIAC FAILURE: In congestive heart failure, inhibition with beta-blockade carries the ntial hazard of further depressing myocardial contractility and precipitating cardiac e. In patients already receiving digitalis, propranolol may reduce the positive inotropic n of digitalis and may have an additive depressant effect on AV conduction.

PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, in rare instances, cardiac e has developed during propranolol therapy. At the first sign of impending cardiac e, patients should be fully digitalized and/or given a diuretic, and observed closely. ardiac failure continues, despite adequate digitalization and diuretic therapy, pro- olol should be immediately withdrawn; b) if tachyarrhythmia is being controlled, nts should be maintained on combined therapy and closely followed until threat of ac failure is over.

PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of gina and, in some cases, myocardial infarction, following *abrupt* discontinuation of DERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage ould be gradually reduced and the patient carefully monitored. In addition, when DERAL is prescribed for angina pectoris, the patient should be cautioned against rruption or cessation of therapy without the physician's advice. If INDERAL therapy nterrupted and exacerbation of angina occurs, it usually is advisable to reinstitute DERAL therapy and take other measures appropriate for the management of unsta- angina pectoris. Since coronary artery disease may be unrecognized, it may be ident to follow the above advice in patients considered at risk of having occult ath- sclerotic heart disease, who are given propranolol for other indications.

PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use not been adequately appraised. Give special consideration to propranolol's potential ggravating congestive heart failure. Propranolol may mask the clinical signs of devel- or continuing hyperthyroidism or complications and give a false impression of ovement. Propranolol should be withdrawn slowly, since abrupt withdrawal may be fol- d by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. Pro- olol does not distort thyroid function tests.

PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been ted in which, after propranolol, the tachycardia was replaced by a severe brady- a requiring a demand pacemaker. In one case this resulted after an initial dose of propranolol.

PATIENTS UNDERGOING MAJOR SURGERY, beta-blockade impairs the ability of the to respond to reflex stimuli. Except in pheochromocytoma, propranolol should be rawn 48 hours prior to surgery. In case of emergency surgery, the effects of pro- olol can be reversed by administration of beta-receptor agonists such as isopro- ol or levarterenol, but such patients may be subject to protracted severe hypotension. ulty in restarting and maintaining the heart beat has been reported.

PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRON- IS, EMPHYSEMA), administer with caution, since propranolol may block bronchodila- roduced by endogenous and exogenous catecholamine stimulation of receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia, especially in patients with labile diabetes. A precipitous elevation of blood pressure may accompany hypoglycemic attacks.

USE IN PREGNANCY: Safe use in human pregnancy not established. Embryotoxic effects have been seen in animals at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if propranolol is administered, since it may occasionally produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

Observe laboratory parameters at regular intervals. Use with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta-blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains 10 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).

—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains 20 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).

—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains 40 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).

—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains 80 mg propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).

The appearance of these tablets is a trademark of Ayerst Laboratories.

Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).

Store at room temperature (approximately 25° C).

Long-Term Failure Rate and Morphologic Correlations In Porcine Bioprosthetic Heart Valves

FREDERICK J. SCHOEN, MD, PhD, JOHN J. COLLINS, Jr., MD, and LAWRENCE H. COHN, MD

To ascertain relations among site, incidence, and mechanisms of clinically evident failure of porcine bioprosthetic heart valves, the frequency of failure of 1,110 valves in 1,001 adult operative survivors from January 1972 to January 1982 was reviewed and correlated with the pathologic features of 22 consecutive dysfunctional valves. There were 373 mitral, 519 aortic, and 109 double replacements, yielding for study 482 mitral and 628 aortic valves at risk. Infective endocarditis occurred in 1.9% (8 mitral, 7 aortic, and 4 double). Twenty-three valves (13 mitral and 10 aortic) with documented primary dysfunction were explanted, a mean of 55 months (range 9 to 94) after surgery. The primary dysfunction rate for the 333 valves implanted for ≥5 years was 6.8% (11 of 161) for mitral and 4.1% (7 of 172) for aortic valves. Valves implanted for <5 years had a failure rate of 0.7%. The actuarially determined freedom from primary valve failure wa 98 ± 1% for mitral and 98 ± 1% for aortic valve at 5 years and 79 ± 7% for mitral and 91 ± 4% fo aortic valves at 10 years. Recovered valves (1 mitral and 10 aortic) with detailed morphologi analysis were functioning for a mean duration of 5 months (range 12 to 87). Causes of failure include calcification-related tears in 7 (4 mitral and 3 aortic mean 66 months), tear without calcium deposits i 4 (4 mitral, mean 44 months), cuspal stiffenin without tear but with calcium deposits in 2 (1 mitra and 1 aortic, mean 80 months) and thrombosis in (aortic). Late primary dysfunction was most fre quently a result of degenerative processes, espe cially calcification, often with secondary tears, bu cuspal tears in the absence of calcium deposits an thrombosis predominated at shorter intervals.

Since their introduction in 1970, glutaraldehyde-preserved porcine aortic valve bioprostheses have performed satisfactorily in most adult patients for up to 10 years.[1–5] Nevertheless, they often fail relatively early in children,[6–10] and there is considerable uncertainty regarding the frequency of late dysfunction in adults. Although morphologic aspects of valve degeneration and dysfunction have been described,[11–15] the mechanisms of such failure remain poorly understood. This report examines the failure rate of 1,110 glutaraldehyde-preserved porcine bioprostheses in 1,001 operative survivors at the Brigham and Women's Hospital (formerly the Peter Bent Brigham Hospital) between January 1972 and January 1982, and correlates these data with the pathologic features of 22 consecutivel analyzed failed valves, to obtain relations among site incidence, and mechanisms of failure.

From the Departments of Pathology and Surgery, Division of Thoracic and Cardiac Surgery, Brigham and Women's Hospital and Harvard Medical School, Boston, Massachusetts. Manuscript received September 3, 1982; revised manuscript received and accepted November 8, 1982.

Address for reprints: Frederick J. Schoen, MD, PhD, Department of Pathology, Brigham and Women's Hospital, 75 Francis Street, Boston, Massachusetts 02115.

Methods

Clinical: The clinical characteristics of the 1,074 adul patients who underwent intracardiac valve replacement witl the Hancock porcine bioprosthetic heart valve during th study period are summarized in Table I. The 1,001 operativ survivors (93% overall survival rate)—373 with mitral, 51 with aortic, and 109 with double valve replacements—forn the basis of the clinical portion of this study. For portions o this analysis, the mitral and aortic valves implanted in pa tients undergoing simultaneous aortic and mitral valve re placement are added to the numbers of single valves at eacl location. Thus, there were 482 mitral plus 628 aortic (total o 1,110) valves at risk for failure. During this period porcin bioprosthetic valves were used to replace cardiac valves in 66% of all adults operated on for valvular heart disease at ou hospital.

All patients undergoing bioprosthetic mitral valve re placement, either alone or in combination with aortic valv replacement, were given the anticoagulant warfarin sodiun for 4 to 6 weeks postoperatively. Warfarin was then graduall

Range	35–68	18–82	18–82

pered over a 2-week period unless the patient had an in-
acardiac thrombus or an enlarged left atrium with chronic
rial fibrillation. No patient with an aortic bioprosthesis was
ven anticoagulant medication initially after surgery.

Follow-up data were obtained by patient examination or
report from the family physician or cardiologist and were
mpleted between December 1981 and March 1982. Causes
death were determined from hospital autopsy records,
roner reports, or, where necessary, clinical data only. Valve
llure was defined as clinically evident dysfunction due to
imary tissue failure with or without calcification, critical
enosis with or without stent creep, thrombosis, or infective
docarditis. The details of the statistical analysis, in which
e cumulative probability of valve dysfunction was estimated
ing the life-table model, were previously reported.[4] All
merical data are reported as the mean ± standard error of
e mean.

Pathology: The failure modes of 22 consecutive dysfunc-
nal Hancock porcine bioprostheses obtained at reoperation
various indications (19) or at autopsy (3) of 21 patients
ring a 2-year period at our hospital were analyzed. There
re 12 mitral and 10 aortic valves implanted for a mean of
months (range 12 to 87) in patients with a mean age of 50
ars (range 22 to 68). During this period 3 additional
oprostheses (all mitral) were surgically explanted for
ravalvular leaks; they are not included in this study. Some
ostheses removed at our hospital and analyzed in the mor-
ologic portion of this study were originally implanted at
her hospitals.

Each valve received was fixed in formalin, described grossly,
otographed from both inflow and outflow aspects, and ra-
ographed (40 kV by 0.8 min) (Faxitron Model 43805, Hew-
t-Packard, McMinnville, Oregon). Multiple specimens were
ken of the valve cusps at their centers and at their com-
issures, embedded in either paraffin or glycolmethacrylate
edium (JB4, Polysciences, Warrington, Pennsylvania) or
th, sectioned at 6 μm (paraffin) or 1 to 3 μm (plastic), and
ained with hematoxylin and eosin. Selected sections were
ained with Gram's stain (for bacteria) or by von Kossa's method (for calcium phosphate). Additional decalcified specimens were embedded in paraffin, sectioned, and stained.

Results

Frequency of dysfunction: The frequency of primary valve dysfunction for both mitral and aortic bioprostheses and the clinical characteristics of the patients in whom these valves were dysfunctional are summarized in Table II. In the total group of 482 mitral and 628 aortic valves, the frequency of primary valve dysfunction was 2.7% for mitral and 1.6% for aortic, an overall frequency of 2.1%.

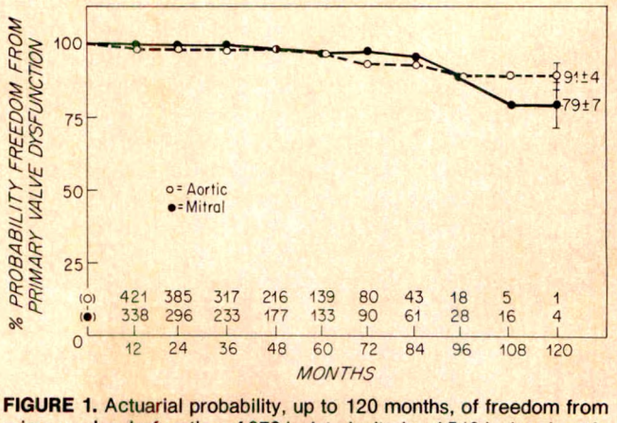

FIGURE 1. Actuarial probability, up to 120 months, of freedom from primary valve dysfunction of 373 isolated mitral and 519 isolated aortic valve replacements including all intrinsic valve failures in the absence of infective endocarditis. **Figures above the time axis** denote numbers of patients at risk at each time interval. **Bars** denote value ± standard error of the mean.

TABLE III Temporal Incidence of Primary Valve Dysfunction (PVD)

Year of Surgery	Mitral Bioprostheses: At Risk/With PVD	Aortic Bioprostheses: At Risk/With PVD	All Prostheses: At Risk/With PVD
1972	17/2	15/0	32/2
1973	28/4	18/0	46/4

Total implanted 0–5 yr	321/2 (0.6%)	456/3 (0.7%)	777/5 (0.6%)
Total (0–10 yr)	482/13 (2.7%)	628/10 (1.6%)	1,110/23 (2.1%)

* One dialysis patient with aortic and mitral bioprostheses had PVD of both.

The yearly incidence of primary valve dysfunction is presented in Table III. Failure of bioprostheses seems to be a time-related process. There have been 11 primary failures in the 161 mitral bioprostheses implanted at least 5 years (an incidence of 6.8%) and 7 primary failures (4.1%) of the 172 aortic bioprostheses implanted before January 1977. The cumulative rate of failure f all prostheses implanted >5 years was 5.4%. In contras the incidence was extremely low in either site, less tha 1%, for bioprostheses implanted for <5 years.

On an actuarial basis the calculated probability freedom from primary valve dysfunction was 98% f isolated mitral and 96% for isolated aortic replacemen at 5 years and 79% for mitral and 91% for aortic at 1 years (Fig. 1). Although not yet of statistical differenc the data suggest that the failure rate of mitral biopro theses is higher than that of aortic bioprostheses.

Infective endocarditis in this patient group involve 8 patients with mitral valve replacements (2.1%), 7 wit aortic valve replacements (1.3%), and 4 with doub valve replacements (3.7%), an overall incidence of 19 1,001 cases or 1.9%. The actuarially calculated prob bility of freedom from endocarditis at 10 years with a bioprostheses was 90 ± 4%. This figure compares wit the probability of freedom from endocarditis at 10 yea with mechanical valve prostheses of 98 ± 1% at o hospital.

Figure 2 shows the actuarially calculated probabili of freedom from both infective endocarditis and pr mary valve dysfunction for isolated mitral and isolate aortic valve replacements. These probabilities were ± 2% for mitral and 96 ± 1% for aortic at 5 years and ± 7% and 84 ± 5%, respectively, at 10 years.

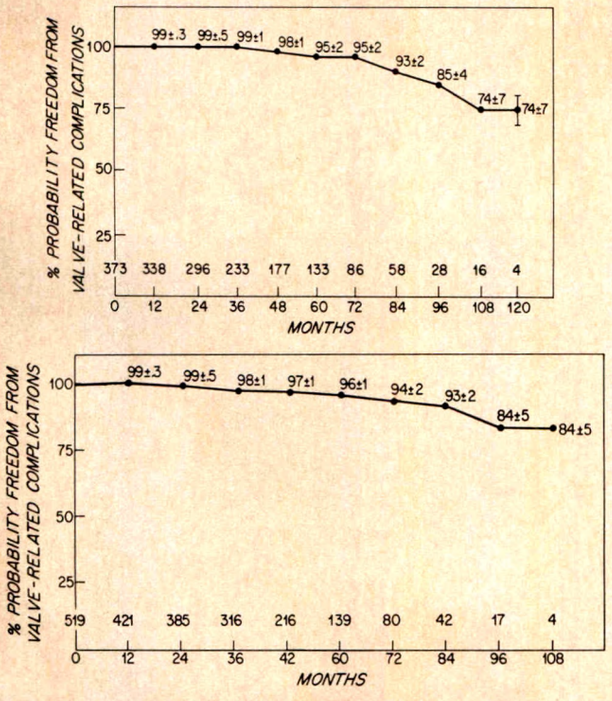

FIGURE 2. Actuarial probability, up to 120 months, of freedom from all local valve-related complications, including primary valve dysfunction and infective endocarditis for (**top**) 373 isolated mitral and (**bottom**) 519 isolated aortic bioprostheses at risk. **Figures above the time axis** denote numbers of patients at risk at each time interval. **Bars** denote value ± standard error of the mean.

Morphologic correlations: Table IV summariz the clinicopathologic characterization of the 22 retrieve bioprosthetic valves. Four patients were operated because of primary cuspal tears of mitral prostheses the absence of calcification. These cuspal defects varie in size from minimal to complete cuspal dehiscence (Fi 3). All but 1 occurred as relatively early events, that i in the first 4 years after the original surgery.

Bioprosthetic dysfunction was commonly associate with cuspal calcific deposits (Fig. 4). The largest sing failure group was that of calcification-related tear These prostheses had substantial cuspal defects ass ciated with variable amounts of calcific material in th

BLE IV Failed Valve Clinicomorphologic Data Summary

Clinicopathologic Process	n (M/A)	Duration (mo)		Range of Cuspal Defect	Range of Calcification
		Mean	Range		
Primary tear	4 (4/0)	44	12–84	+/+++	0
Calcification with tear	7 (4/3)	66	44–87	++/+++	+/+++

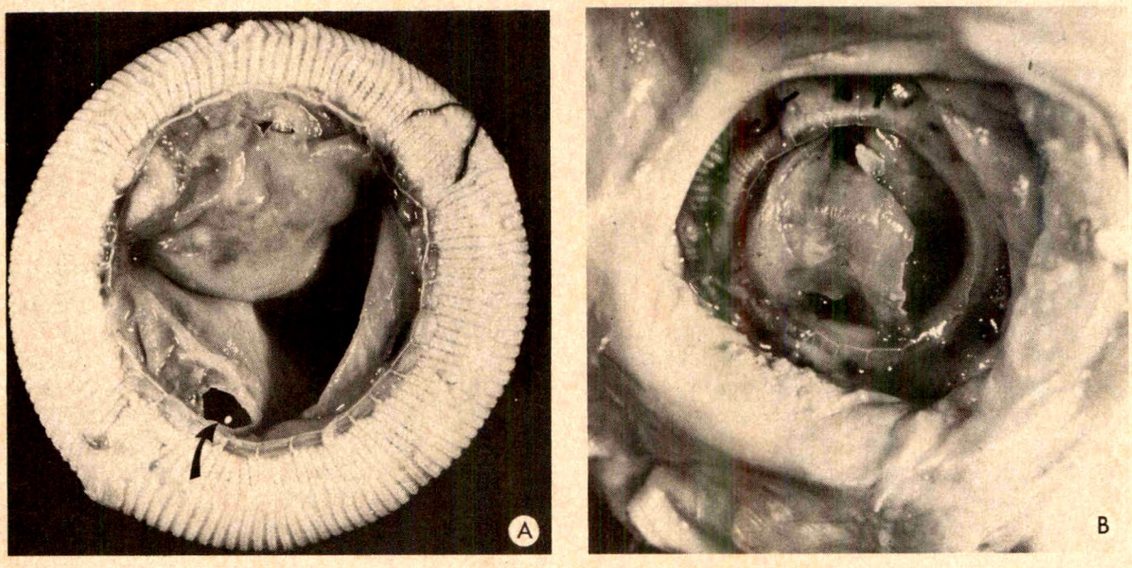
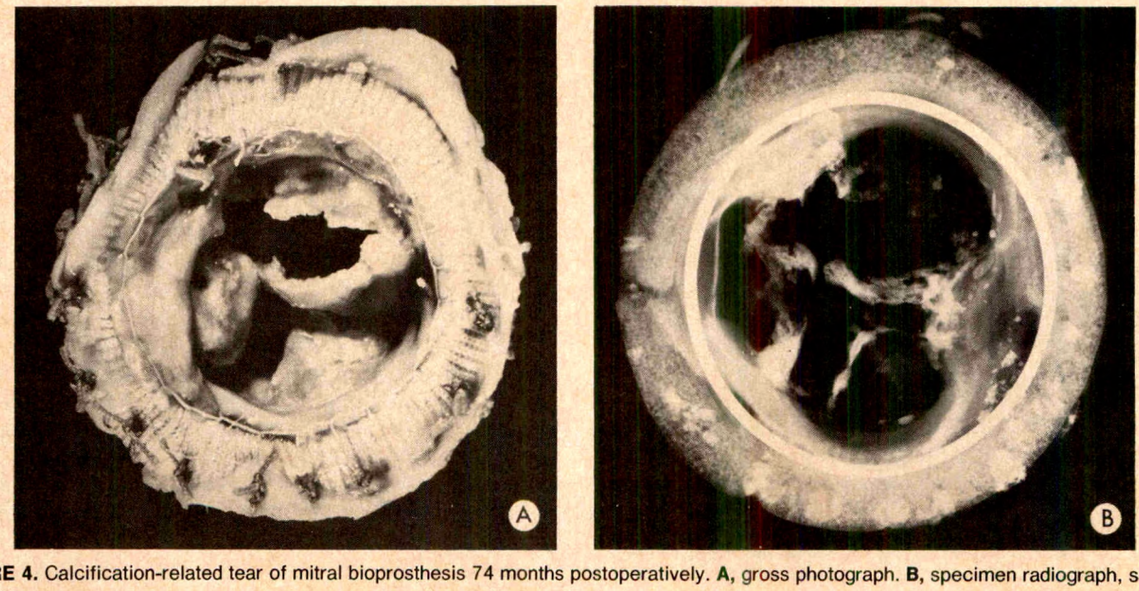
Endocarditis	8* (3/5)	45	23–81	0/++	0/++
Thrombosis	1 (0/1)	12	. . .	0	0

One patient had endocarditis of both mitral and aortic valves.
- = mild; ++ = moderate; +++ = severe. A = aortic; M = mitral.



URE 3. Gross photographs showing range of primary cuspal tears in the absence of calcification. **A,** small perforation at base of cusp of mitral prosthesis after 84 months (**arrow**). **B,** complete dehiscence of cusp of mitral bioprosthesis. This patient was not reoperated on because of medical considerations and died 47 months after original surgery.



URE 4. Calcification-related tear of mitral bioprosthesis 74 months postoperatively. **A,** gross photograph. **B,** specimen radiograph, same orientation.

cusps (Fig. 4). Early calcification predominated in commissural regions of the cusps and was generally associated with severe collagen deterioration observed by light microscopy. Early calcific deposits were seen in both spongiosa and fibrosa of the porcine valve cusps. However, in many cases the cuspal architecture was so poorly preserved that precise anatomic localization was difficult.

Two patients had bioprosthetic stenosis in the absence of cuspal defects. One of these patients had a mitral valve prosthesis implanted for 85 months. Fine calcifications were revealed by radiography and histologic study at the cuspal commissures. Another patient presented with aortic bioprosthetic stenosis associated with considerable cuspal calcifications after 75 months of implantation.

Eight prosthetic valves with infective endocarditis were retrieved from 7 patients after 23 to 81 months. Bioprosthetic endocarditis often involved the va cusps themselves and was commonly quite destruc (Fig. 5A). The sewing ring was involved in several ca Deposition of calcium precipitates occurred seconda in the vegetations in most cases of endocarditis (5B), and generally predominated at the free cus edges (Fig. 5C). Ring abscesses occurred in 3 patie One patient died suddenly from subtotal stenosis o aortic prosthesis due to Streptococcus intermedius fection with superimposed thrombosis (Fig. 6). rombotic deposits were predominantly on the out-
v surfaces of the prosthetic cusps (sinuses).

Discussion

Tissue valve replacements for diseased cardiac valves
e, as major advantages over mechanical prostheses,
w risk of thromboembolism, usually without anti-
gulation, and central flow characteristics. Failure of
chanical valve prostheses is often catastrophic, but
ny complications associated with biologic valve re-
cement are often slow in onset and therefore most
ients with such complications may successfully un-
go reoperation.

Time-dependent rate of failure: Mitral versus tic bioprostheses: This study describes the rate of
ical bioprosthetic valve dysfunction in a series of
10 such replacements in 1,001 adults over a 10-year
iod. Infective endocarditis was documented in 19
ients (1.9%). Primary valve dysfunction occurred in
aortic and 13 mitral valve replacements. In the lim-
l series with a minimum 60-month follow-up period,
re were 161 mitral and 172 aortic valve replacements.
e primary dysfunction rate was 6.8% for mitral
stheses and 4.1% for aortic. In 777 valves implanted
years the failure rate was <1%. The actuarial prob-
lity of valves being free of primary tissue dysfunction
6 months was 79 ± 7% for mitral valves and 91 ± 4%
aortic.

n the present study, porcine bioprosthetic valves in
mitral position failed more frequently than did those
in the aortic position. Several reasons for the disparity in failure rate between mitral and aortic prostheses are plausible. In studies of fatigue damage of glutaraldehyde-preserved porcine heart valve tissue, Broom[16] demonstrated that compressive flexure is more significant than tensile loading in its contribution to disruption of tissue integrity and potential long-term durability of bioprostheses. A recent biomechanical study suggests that such compressive stresses occur in vivo during valve opening and may explain degeneration of these valves.[17] The larger-sized mitral bioprostheses would be expected to have higher stresses than the aortic bioprosthesis.

However, the most plausible hypotheses that would account for a greater frequency of failure of mitral bioprostheses relative to aortic consider the closed valve. The diastolic pressure differential across the aortic prosthesis would be approximately 75 mm Hg compared with 115 mm Hg across the mitral prosthesis. Furthermore, the rate of closure is expected to be greater with a mitral compared with an aortic prosthesis.

The present study did not consider the possible late development of asymptomatic stenosis in patients whose condition was clinically stable, as suggested by Lipson et al[18] in a study of patients with mitral bioprostheses after extended postoperative intervals.

Primary disease of bioprosthetic heart valves: Logistical difficulties associated with auto- and allografts prompted the use of xenograft tissue for cardiac valve replacement. Study of formalin-preserved porcine

ocarditis (Streptococcus intermedius) with subtotal prosthetic
osis by vegetation with superimposed thrombus.

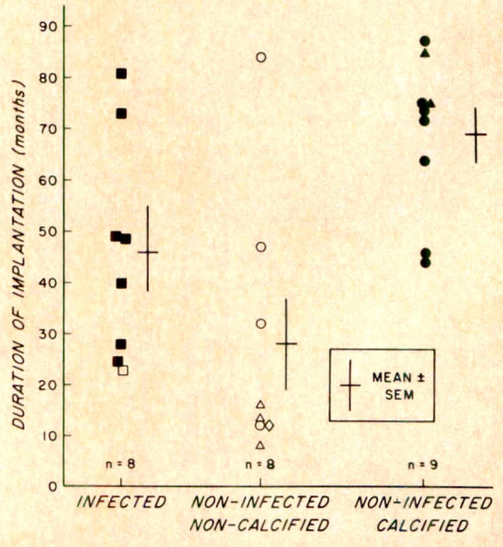

FIGURE 7. Relation of calcification to duration of implantation for infected and noninfected retrieved bioprosthetic heart valves. Calcification of infected valves is independent of postoperative interval. Calcification in noninfected bioprostheses is generally encountered only after approximately 4 years of service and only in some patients. **Open squares** = endocarditis, noncalcified; **closed squares** = endocarditis, calcified; **open circles** = cuspal tear, noncalcified; **closed circles** = cuspal tear, calcified; **open diamonds** = thrombosis; **open triangles** = paraprosthetic leak; **closed triangles** = stenosis with calcification. **All filled symbols** represent calcified valves. SEM = standard error of the mean.

aortic valves used as human aortic bioprostheses shows (up to 45 months after implantation) progressive changes involving loss of cells, collagen and elastin degeneration, ingrowth of host inflammatory cells, and cuspal rupture.[19,20] Available since 1970, glutaraldehyde-preserved flexible stent-mounted porcine aortic valve bioprostheses have gained wide acceptance in the replacement of diseased cardiac valves. Clinical performance has been satisfactory in most adult patients over an extended follow-up.[1–5] However, bioprostheses often fail relatively early in children,[6–10] probably because of age-related accelerated calcium metabolism.

Clinically significant valvular dysfunction is uncommon, and pathologic changes at the level of light microscopy are slight in the immediate postoperative period with glutaraldehyde-preserved porcine bioprostheses.[11,12] Nevertheless, scanning and transmission electron microscopic examination of unimplanted valves shows loss of endothelium and acid mucopolysaccharides during preimplantation processing.[13] Short-term (<1 to 2 months) changes after implantation consist of insudation of plasma proteins, penetration of erythrocytes into surface crevices, formation of a thin surface layer of fibrin, and deposition of macrophages, giant cells, and platelets. Long-term (>2 months) changes are time-related and consist of progressive disruption of collagen, erosion of the valve surfaces, formation of platelet aggregates, and accumulation of lipid. Although cuspal surfaces may become partially covered with endothelium, this event occurs late.[21]

Clinically significant late deterioration with or without thrombosis or calcification of these valves in the absence of antecedent endocarditis (primary tissue failure) is now encountered in some adult patients after 4 to 5 years of implantation.[1–5,22] In some cases, tearing and destruction or rigidity of valve cusps is associated with valvular thickening assessed by echocardiography.[23] In failed valves, characteristic time-related microscopic changes include fibrin deposition on and inflammation in the valve cusps, focal disruption of the cuspal fibrocollagenous matrix, and calcification.[13–15] Calcific deposits occur commonly in bioprostheses implanted in patients of all ages, but are more likely to become severe and clinically significant in children and young adults than in older patients. Although renal failure was present in several reported patients with early calcification, pertinent metabolic disorders are not identified in most patients with calcified prosthetic tissue valves. The 2 main sites of deposition of calcium phosphate in porcine valve bioprostheses are the connective tissue in the cusps, particularly in the spongiosa, and small thrombi on the surfaces.[14] An additional group of patients has gross disruption of cuspal integrity with tears in the absence of calcific deposits. Such defects may occur at any time after surgery, but usually occur within the first few years and are often associated with changes in collagen structure which account for their origin.[15]

Clinicopathologic failure modes: The morphologic observations we report are consistent with those of previous studies described herein and emphasize that

dysfunction of porcine bioprostheses takes mul
major clinicopathologic forms. Primary tissue fa
may occur relatively early in the absence of calcific
and is due to disruption of the fibrocollagenous sup
network of the valve. These failures take the for
commissural tearing or basilar linear perforations (
I and II lesions described by Ishihara et al[15]). O
patients with such tears had mitral bioprostheses

The most frequent mode of primary valvular
function in our study was calcification-associated
in the absence of endocarditis. Early deposits wer
calized at the commissures. More severe cases
generalized calcifications. Tears in calcified valves
generally large. All such valves were in place for
months (mean 66). One mitral and 1 aortic prostl
had thickening and stiffening of the valve cusps wit
perforation or tear. These 2 patients had a clinical
ture compatible with stenosis and the valves had ca
deposits.

Bioprosthetic infective endocarditis: As wi
mechanical cardiac valve prosthesis, infection
porcine bioprosthesis is a serious complication.
Although our incidence of endocarditis is lower
mechanical prostheses than with bioprostheses, ot
report a similar incidence (approximately 1%)
mortality rate (approximately 33%) for infection
bioprostheses and mechanical prostheses.[24] With
types of prostheses, aortic valve infections are gene
more common than mitral. With mechanical prosth
infection is initiated at the host tissue/prosthesis se
ring junction. Although sewing ring infection may o
with bioprostheses, infection often solely involves
cuspal tissue.[25] Medical therapy may thus sterilize s
of these infections.[24] However, infection of por
bioprostheses in contrast to mechanical prostheses
involve and destroy the prosthetic material it
leading in some cases to stiffening, calcification,
perforation of the valve cusps.[25,26] Although it has
suggested that valve ring abscesses and perivalv
leaks are uncommon in porcine valve infection, t
complications certainly do occur and may have the s
catastrophic consequences as does mechanical p
thetic valve endocarditis.

Comparison of Late Degenerative Changes in Porcine Bioprostheses in the Mitral and Aortic Valve Position in the Same Patient

CAROLE A. WARNES, MB, BS, MRCP, MEREDITH L. SCOTT, MD, GARY M. SILVER, MD, CLAUDE W. SMITH, MD, VICTOR J. FERRANS, MD, PhD, and WILLIAM C. ROBERTS, MD

Porcine bioprostheses implanted in both the mitral and aortic valve positions simultaneously in 5 patients aged 20 to 61 years (mean 45) were reexamined 18 to 107 months (mean 51) later. In 4 patients, the degenerative changes were distinctly more severe in the bioprostheses in the mitral than in the aortic valve position.

Many reports have described degenerative changes in porcine bioprostheses implanted in either the mitral or aortic valve position.[1–5] None, however, have described morphologic alterations in bioprostheses in both positions in the same patient. The latter situation, of course, allows one bioprosthesis to serve as a control for the other. This report summarizes clinicopathologic findings in 5 patients in whom porcine aortic bioprostheses had been implanted 18 to 107 months earlier in both mitral and aortic valve positions.

Patients Studied

Clinical findings: Clinical and morphologic findings in the 5 patients are summarized in Table I. At the time of initial double valve replacement, the 5 patients (4 men) ranged in age from 20 to 61 years (mean 45). Late postoperatively, chronic congestive heart failure developed in 4 (all but Patient 1), and 3 of them (Patients 2, 3, and 5 [Table I]) had their malfunctioning bioprostheses in both the mitral and aortic valve positions excised, and replaced with mechanical prostheses. The remaining patient (Case 4), who had chronic congestive heart failure, died from complications of primary biliary cirrhosis before her malfunctioning bioprosthesis in the mitral position could be replaced. The 1 patient (Case 1) without clinical evidence of congestive cardiac failure c prosthetic valve dysfunction died from complications of ha bitual alcoholism.

Morphologic findings: The 10 bioprostheses are illus trated in Figures 1 to 5. Each cusp was thicker than norma and *cuspal mobility* appeared distinctly diminished in bioprostheses (3 mitral and 2 aortic). Each of these bioprostheses appeared on visual inspection to have som degree of obstruction, and catheterization in 2 patients (Case 2 and 3) confirmed bioprosthetic stenosis in both mitral an aortic positions.

Calcific deposits were present in 1 or more cusps in all 1 bioprostheses. In 4 of the 5 patients, the calcific deposits wer clearly larger on the cusps of the bioprostheses in the mitra position than on the cusps in the aortic position. In 2 patient (Cases 3 and 5) *cuspal tears* were present, and they also in volved only the bioprostheses in the mitral positior Bioprosthetic *thrombus* was present only in the patient (Cas 2) with infective endocarditis.

Of the 2 patients in whom the bioprostheses had been i place for <2 years, 1 (Patient 1) had mild degenerativ changes in both valves, those in the aortic position bein slightly more marked. The other patient (Case 2) whos bioprosthetic valves deteriorated rapidly had clinical an morphologic evidence of infective endocarditis; vegetations present on both bioprostheses, contained fungi and bacteria but no inflammatory cells, cuspal tears, or perforations.

Discussion

Examination of the bioprostheses located in bot mitral and aortic valve positions clearly demonstrate in 4 of the 5 patients greater degeneration of th bioprosthetic cusps located in the mitral valve positio than in those in the aortic valve position. The reason

for the more extensive degeneration of the bioprostheses in the mitral position are unclear but at least 4 factors need consideration.

1. The closing pressure on the bioprosthesis in the mitral position is higher than that on the bioprosthesis in the aortic position.

2. The pressure difference across the closed bioprosthesis in the mitral position is far higher than that across the closed bioprosthesis in the aortic position. The higher the pressure difference across the closed bioprosthesis, the greater the tensile stress on the cusps.[6]

3. The presence of a bioprosthesis composed of a semilunar valve in the atrioventricular valve position

may prevent equal distribution of the left ventricular systolic pressure on each of the 3 bioprosthetic cusps (Fig. 6), whereas the aortic diastolic pressure is probably equally distributed on each of the 3 aortic valve cusps.

4. Sinus rhythm theoretically causes more work for the cusps of a mitral valve than for the cusps of an aortic valve, as atrial contraction partly reopens the valve. In contrast, the aortic valve opens only once during each cardiac cycle. The "double movement" of mitral opening when the mitral valve consists of an

Phonocardiographic Findings in Patients With Normally Functioning Ionescu-Shiley Prostheses

ROMAN L. SZKOPIEC, MD, KENNETH B. DESSER, MD, ALBERTO BENCHIMOL, MD, and CONNIE SHEASBY

Phonocardiographic findings are reported in 19 patients with normally functioning Ionescu-Shiley prostheses in the mitral or aortic position. Opening clicks were recorded in all 8 patients with mitral prostheses at a mean second heart sound (A2) to opening click interval of 94 ms. In 9 subjects, apical systolic murmurs were found. All 11 patients with the prosthesis in the aortic position had systolic ejection murmurs. Opening clicks were observed in 8 patients with a mean Q wave to opening click interval of 125 ms; closing clicks were found in 9 of 11. No diastolic murmurs occurred in this group. These acoustic characteristics serve as a reference source for the noninvasive evaluation of the bovine pericardial prosthesis.

In the follow-up of a group of clinically stable patients who had received the Ionescu-Shiley pericardial xenograft heart valve, we sought to document the murmurs and clicks heard during auscultation.

Methods

Phonocardiograms were recorded in 19 patients aged 42 to 63 years who had undergone valve replacement with the Ionescu-Shiley prosthesis. Eight had the prostheses implanted in the mitral position and 11 in the aortic position. Table I summarizes the diagnostic findings at the time of cardiac catheterization before surgical intervention, as well as the lapse of time from operation to the time of the study (range 1 to 16 months, mean 6).

The records were obtained with a commercially available Electronics for Medicine VR12 simultrace recorder, and an Irex phonorecorder. Leatham-type microphones were applied in all cases. Phonocardiograms were systematically evaluated for clicks, murmurs, and other transient sounds. The following measurements were made on the recordings from subjects with aortic prostheses: Q wave to opening click interval and relationship of closing click to dicrotic notch on the simultaneously recorded external carotid arterial pulse tracing. For those with mitral prostheses, the second heart sound to opening click interval was measured.

Results

All 8 patients with the Ionescu-Shiley pericardial xenograft in the mitral position had a loud sound after the second heart sound (Fig. 1). Appropriate filtering indicated that this sound had high frequency characteristics (Fig. 2). Simultaneous left ventricular apexcardiography disclosed that the sound was inscribed concurrent with the O point, suggesting that it was associated with prosthetic opening (Fig. 3). The second heart sound-opening click interval ranged from 80 to 120 ms, with a mean of 94 (Table I). Seven of these subjects also had a change in the quality of the first heart sound, which acquired closing click-like characteristics. The mean Q wave to closing sound interval ranged from 70 to 100 ms with a mean of 80 (Table I). In 7 of 8 patients, low amplitude, high frequency murmurs were recorded. In 3 of the subjects, the murmurs were ejection in quality; the other 4 were holosystolic. These murmurs were heard and recorded best at the mitral and pulmonary areas. In 2 of the patients, early diastolic murmurs were recorded. One of these patients had aortic insufficiency and the other had severe pulmonary hypertension.

In 9 of the 11 patients with aortic prostheses, we found loud high frequency sounds preceding the dicrotic notch of the carotid arterial pulse by a mean interval of 16 ms. In 8 of these subjects, lower amplitude, high frequency sounds were recorded after the Q wave by a mean interval of 125 ms (Fig. 4 and Table I). Early systolic ejection murmurs were heard and recorded in all 11 patients in this group; the murmurs were loudest in the pulmonary and tricuspid areas. No diastolic murmurs were recorded in this group of patients.

Discussion

Ionescu et al[1,2] reported the development of heart murmurs in 3.9% of their large series after implantation of the pericardial valve prosthesis. Phonocardiographic study in subjects with this xenograft should be useful since such recording has aided in the detection of porcine valve malfunction through the development of new clicks, changes in the spectral frequency of the closing sound,[3] and new murmurs.[4,5]

Note that the opening click (OC) is inscribed in conjunction with the apex-cardiographic O point. CC = closing click.

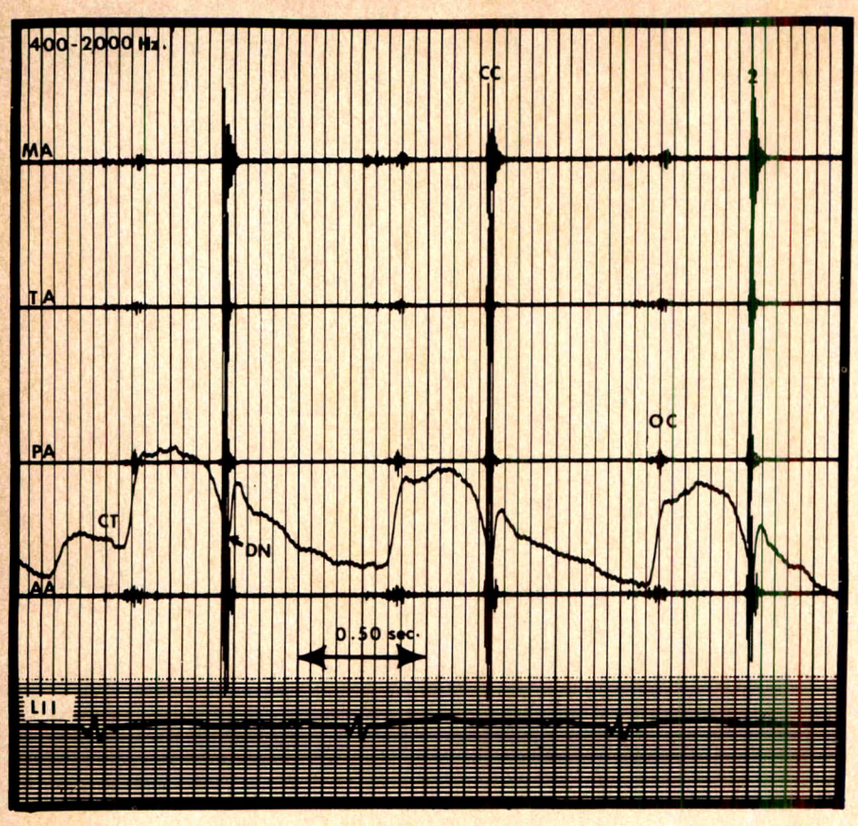

FIGURE 4. Phonocardiograms, external carotid pulse tracing, and lead II of electrocardiogram from a patient with an Ionescu-Shiley prosthesis in the aortic position. Note the high amplitude, high frequency closing click inscribed in conjunction with the dicrotic notch. A low amplitude, high frequency opening click follows the first heart sound. Abbreviations as in Figure 1.

Soft opening sounds have been reported occasionally in patients with a porcine heterograft in the mitral position.[4] The apparent rarity of such sounds, however, would mitigate utility of the second heart sound to mitral valve opening interval, which has been proven valuable in the detection of mechanical valve obstruction or paravalvular leak.[6–9] In particular, lengthening or shortening of the second heart sound to mitral valve opening indicates valvular obstruction and paravalvular leak, respectively, in this setting.[6,9]

In contradistinction to the porcine mitral xenograft, we found that the Ionescu-Shiley pericardial valve in the mitral position uniformly produces an opening click. It is of interest that the mean second heart sound to opening sound interval was 94 ms because this value correlates well with opening click times cited for the normally functioning mechanical prosthesis in the mitral position.[6] Further study is needed in order to determine whether or not alteration of this interval has the same clinical significance for the detection of Ionescu-Shiley mitral valve dysfunction.

In the series reported by Ionescu and Tandon,[1] 10.5% of the patients with the pericardial xenograft in the aortic position had early diastolic murmurs shown to be secondary to paravalvular leak. None of our subjects had suspected aortic leaks, yet all had systolic ejection murmurs. These murmurs can be attributed to turbulent flow through the prosthesis. Opening clicks were recorded in 8 of these patients with Ionescu-Shiley aortic valve prostheses. We found a mean Q wave to opening sound interval of 125 ms in our study group; this accords well with aortic opening click times in groups of patients with mechanical prostheses.[8,9] Attenuation or disappearance of this aortic opening click in subjects with the Ionescu-Shiley valve may serve to indicate valve failure in long-term serial study.

In conclusion, the Ionescu-Shiley valve xenograft manifests acoustic qualities which resemble, in part, those of mechanical prostheses. In contrast to porcine valves, the opening sounds are frequent and may provide a basis for simple noninvasive follow-up by auscultation and phonocardiography.

M-Mode and 2-Dimensional Echocardiographic Characteristics of the Ionescu-Shiley Valve in the Mitral and Aortic Positions

ROMAN L. SZKOPIEC, MD, JEREMY TORSTVEIT, MD, KENNETH B. DESSER, MD, RAJENDRA D. SAVAJIYANI, MD, ALBERTO BENCHIMOL, MD, and DENZIL K. SOLOMON

Using M-mode and 2-dimensional (2-D) echocardiography, ultrasonic features of the Ionescu-Shiley valve were characterized. A number 23 prosthesis was placed in a saline-filled chamber and subjected to pulsatile flow. Production of a linear tear at the base of a cusp resulted in coarse fluttering in the open position, and there was a reduction in the anterior cusp slope. Partial detachment of a cusp from its stent produced high-amplitude low-frequency fluttering during ejection. Alteration of transducer position eliminated the abnormal echoes. Fourteen patients with aortic and 11 with mitral prostheses were studied. There was a close approximation of echographically determined values for the bare stent internal diameter, cusp excursion, and valve orifice diameter compared with the manufacturer's specifications. Random punctiform echoes were noted when the cusps opened. Cusp echoes were superimposed on stent echoes in 21% of patients, and a third cusp was detected in 29%. Two-dimensional echocardiograms of good quality were recorded in the vast majority of subjects. Cusp echoes were smooth and had a consistent motion in both the short and longitudinal axis. Multiple transducer positions were required to delineate prosthetic components with optimal clarity. It is concluded that (1) M-mode and 2-D echocardiography is useful in assessing Ionescu-Shiley valve function, (2) in vitro valve tears or detachment produces characteristic cusp fluttering, (3) careful attention to transducer positions is necessary to record high-quality valve images, and (4) these findings represent a data base for the longitudinal follow-up study of patients with the Ionescu-Shiley valve.

The Ionescu-Shiley pericardial xenograft valve has been shown to have long durability and a low incidence of valve dysfunction and thromboembolism with adequate preservation of the tissue structure in up to 67 months of follow-up.[1–6] The symmetry of its design permits simultaneous cuspal motion and smaller transvalvular gradients than with most porcine heterograft valves. This report describes the echocardiographic features of the normally functioning Ionescu-Shiley pericardial xenograft in vitro and in vivo in both the mitral and aortic positions. We used methods previously employed for ultrasonic study of other bioprostheses.[7–15]

Methods

In vitro study: M-mode and 2-D echocardiograms were obtained from a number 23 Ionescu-Shiley valve before and after it was sewn to an especially constructed nylon conduit. The inflow area of the conduit and valve was connected to the outlet of a commercially available centrifugal pump (DIAL model D-75) which was electronically modified to deliver hemisinusoidal pulsatile flow of saline solution with stroke volumes of 50 to 100 ml. The outflow portion of the conduit was connected to a distensible rubber reservoir, which produced a continuous distal pressure regulated by partly clamping its outlet (Fig. 1). Two-dimensional echocardiograms were obtained with (1) a Smith-Kline EkoSector I (model 2022), (2) a single crystal mechanical transducer (2.25 mHz) swept through a 30° sector, and (3) an Irex phased array sector scanner. M-mode echocardiograms were obtained with Smith-Kline and Irex models.

The images were recorded in a Sanyo VT video cassette and individual frames were photographed with a Polaroid® camera. M-mode echocardiograms were obtained with the ultrasonic beam intersecting the valve at 30° to 40° from the hor-

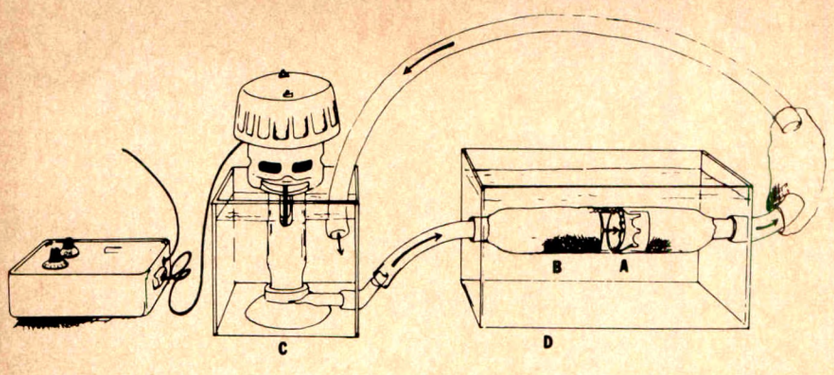

FIGURE 1. Chamber for in vitro echocardiographic studies of Ionescu-Shiley valve. **A,** Ionescu-Shiley valve, size 23; **B,** nylon conduit; **C,** pump; **D,** saline chamber.

izontal and sagittal planes. Two-dimensional echocardiograms in the longitudinal and transverse planes were obtained with the same approach. This examination was repeated after rendering the valve insufficient by (1) producing a 6 mm linear tear in the base of 1 of the cusps, and (2) detaching a single cusp from 1 of its 2 stents.

In vivo study: Twenty-five patients, aged 41 to 68 years, were studied 1 to 12 months after surgery: 14 had aortic and 11 had mitral valve replacement. None had clinical evidence of bioprosthetic dysfunction.

Two-dimensional echocardiograms were obtained in 11 patients, with the prosthetic valve in the aortic position in 6 and in the mitral position in 5. To record optimal echoes from the prostheses, multiple transducer positions were used in addition to the standard acoustic window.[15–17] In general, the cusps required selective setting adjustment, as reported with other bioprostheses.[9,11,12] High-gain dampening and relatively low reject were found more useful for this purpose. The approach described by Schapira et al[14] was used in the 2-D studies. Examinations were performed with the patient in the left lateral position. All measurements represent the mean of 3 consecutive estimations. In the aortic position measurements included the diameter of the leading edges of the stent, internal and external diameter of the stent, internal/external stent diameter ratio, and cusp excursion. In the mitral position similar measurements were made in addition to measurements of the initial diastolic slope of the anterior cusp and stent, systolic anterior excursion of the stent, and left ventricular outflow tract dimension.

The opening motion of the Ionescu-Shiley valve in the aortic position produced a faint, steep, and discontinuous linear echo which was difficult to record. Two-dimensional measurements in both positions included cusp thickness and stent diameter. The following qualitative characteristics established for the porcine prosthesis by other investigators,[13,14,17] were assessed in this study: consistency of cusp motion, changes of prosthetic axis in the longitudinal plane throughout the cycle, concordancy of prosthetic and myocardial motion, quality of echoes arising from the cusps and stents (smoothness), and left ventricular wall motion.

Results

In vitro study: M-mode study revealed 2 parallel echoes 2 to 3 mm wide from the anterior and posterior stents. The measured ultrasonic internal stent diameter of 20 mm was identical to the manufacturer's standard for the number 23 Ionescu-Shiley valve. The band of echoes between those from the stents corresponds with the closed cusps. M-mode measurements after suturing the valve to the nylon conduit showed an increment in width of the stent echoes to a total of 5 to 6 mm. The ultrasonic external stent diameter was 30 mm, thereby resulting in an internal to external diameter ratio of 0.67. Figure 2 shows the valve motion during 4 simulated cycles. The opening diameter of the leading edge echoes of the stent was 2.5 cm. The opening slope of the anterior cusp was 320 mm/s and the closing slope 280 mm/s. The ultrasonic cusp excursion was 18 mm compared with the manufacturer's orifice diameter of 19 mm. Echoes from the cusps in the open position had a width of 1 mm and exhibited dense high-frequency fluttering, contrasting with the linear horizontal echoes from the stent. The third cusp was not visualized, with the ultrasonic beam approaching the prosthesis from the inflow area of the valve at a 30° to 40° tilt to the sagittal and transverse planes. This orientation of the transducer produced optimal echoes and was used to obtain 2-D images, with the stents in positions 10-2-6 o'clock. Identification of the suture ring and the 3 cusps was possible by means of the short-axis plane. The long-axis sector scan disclosed echoes from 2 stents, the ring, and 2 cusps. The opening and closing motion of the Ionescu-Shiley valve cusps was consistently recorded. The cusp echo was 2 mm in width, regular, and smooth. The

long-axis view showed the central position of the closed cusps behind the stents.

M-mode echocardiograms obtained after producing a 5 mm linear tear at the base of the anterior cusp without detachment disclosed intermittent coarse fluttering below the anterior cusp in the open position. Additionally, the closing slope of the anterior cusp was reduced. Detachment of the anterior cusp from a supporting stent and ring attachment to 50% of its extension produced high-amplitude, low-frequency fluttering during ejection (Fig. 3). Alteration of the transducer position eliminated this abnormal echo, thus producing an ultrasonic configuration resembling that of the intact valve.

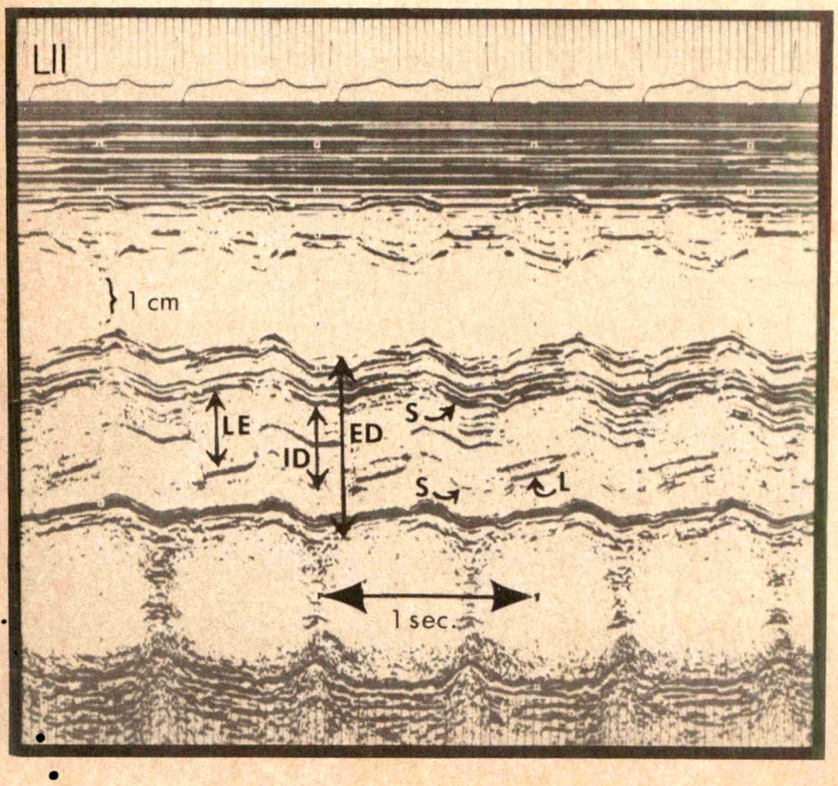

FIGURE 4. In vivo M-mode echocardiogram of the Ionescu-Shiley prosthesis in the aortic position. ED = external stent diameter; ID = internal stent diameter; L = cusp echoes; LE = cusp excursion; LII = lead II of the electrocardiogram; S = stent echoes.

In vivo study: Adequate M-mode echocardiograms were obtained in 13 of 14 patients with the prosthesis in the aortic position and in 9 of 11 patients with the valve in the mitral position. Four of 5 patients with the mitral prosthesis and 5 of 6 patients with the valve in the aortic position had satisfactory results on 2-D examination. Multiple acoustic windows, selective optimization of the settings for the prosthetic cusps, long- and short-axis and hemiaxial views were used.

M-mode values for the aortic prosthesis measurements are presented in Table I and can be summarized as follows: mean (±1 standard deviation) diameter of the leading edge of the stent = 29 ± 3 mm; internal diameter of the stent = 22 ± 3 mm; external diameter of the stent = 36 ± 5 mm; internal/external stent diameter ratio = 0.61 ± 0.07; and cusp excursion = 19 ± 2 mm.

Table II summarizes the comparison between ultrasonic measurements and the manufacturer's bare stent internal diameter, cusp excursion, and diameter of the valve orifice. The internal diameter of the stents was identical to the manufacturer's bare stent inside diameter in 6 of 14 patients (42%), and in 50% of cases the measured value was larger, mean excess being 4 mm (range 1 to 12). In only 1 patient was the measurement 2 mm less than the manufacturer's value. The measured cusp excursion compared with the manufacturer's valve orifice diameter was as follows: in 10 of 13 patients (77%) the mean excess was 1.3 mm (range 1 to 3) and in 23% this value was 3 mm (range 2 to 3) smaller than the actual diameter of the valve orifice. The measured cusp excursion was identical to the manufacturer's bare stent inside diameter in 9 of 13 patients (69%) and smaller in 3 of the 13 patients by a mean of 4 mm. In 1 patient the cusp excursion exceeded the manufacturer's value by 1 mm.

Cusp echoes were superimposed on stent echoes in 21% of patients and a third cusp echo was detected in 29% of subjects. In all patients, random punctiform "snowy" echoes were found especially with the cusps open. The opening motion of the cusps produced very rapid, faint discontinuous linear echoes. The cusp echoes during systole had a width of 1 mm and exhibited a characteristically high-frequency fluttering motion (Fig. 4).

A typical M-mode echocardiogram of a mitral Ionescu prosthesis is shown in Figure 5. M-mode measurements of the mitral prosthesis are presented in Table III and can be summarized as follows: mean diameter of the leading edge of the stent = 26 ± 3 mm; mean internal stent diameter = 23 ± 2 mm; mean external stent diameter = 32 ± 4 mm; internal/external diameter ratio = 0.758 ± 0.08; mean leaflet excursion = 21 ± 2 mm; mean initial diastolic slope of the anterior cusp = 24 ± 8 mm; mean initial diastolic slope of the stent = 23 ± 8 mm.

Comparison of the ultrasonic internal diameter of the stent with the manufacturer's bare stent inside diameter indicated that in 44% of patients, the former manifested a mean excess of 3 mm (range 1 to 6); in 33% the value was 3 mm smaller; and in 22% the measurements were identical. The measured cusp excursion was found to be 1 to 7 mm (mean 3) smaller than the manufacturer's

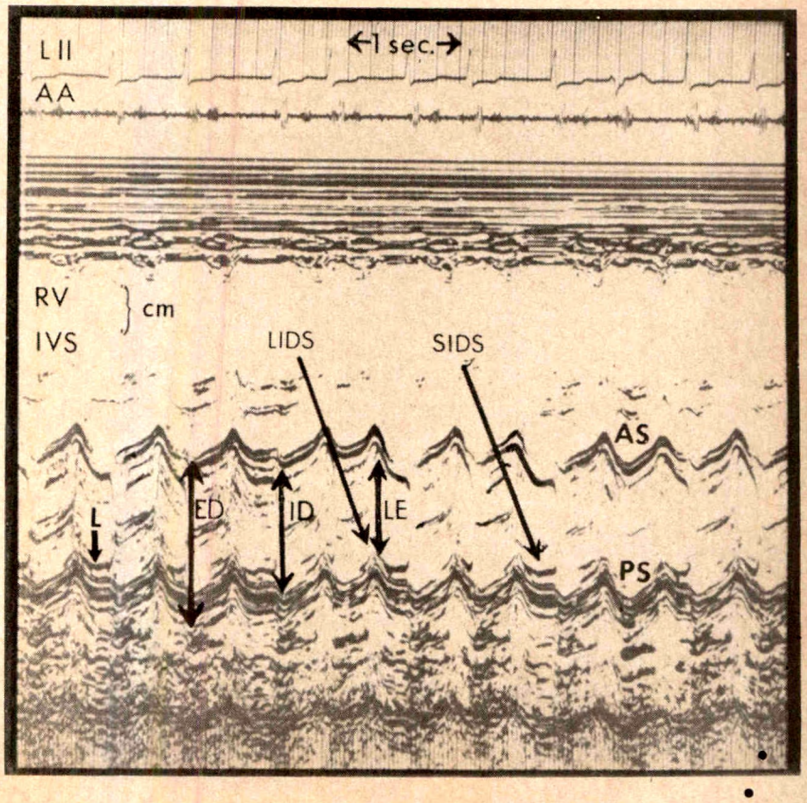

FIGURE 5. M-mode echocardiogram of the Ionescu-Shiley prosthesis in the mitral position. AA = aortic area phonocardiogram; AS = anterior stent; ED = external stent diameter; ID = internal stent diameter; IVS = interventricular septum; L = cusp echoes; LE = cusp excursion; LII = lead II of electrocardiogram; LIDS = initial diastolic slope of cusp; PS = posterior stent; RV = right ventricle; SIDS = initial diastolic slope of stent.

value for orifice diameter in 78% of patients, and in 22% cusp excursion was larger by 1 to 8 mm (mean 4). In 78% of patients, the cusp excursion was 2 to 4 mm (mean 3) smaller than the measured internal stent diameter, whereas in 11% both values were identical. In the remaining 11% of subjects, cusp excursion was 1 mm larger than the internal diameter of the stents (Table IV).

The stents displayed anterior systolic motion and the mean systolic excursion of the anterior stent was 4 mm. Interventricular septal motion was paradoxical in 8 patients, flattened in 7, and normal in 4. The mean left ventricular outflow tract estimation in end-systole was 82 mm and in end-diastole 96 mm. In 6 patients, a third stent echo was observed with varying degrees of eccentricity. The closing cusp position tended to be midway between the anterior and posterior stents. In 2 patients with atrial fibrillation and R-R intervals >1,200 ms, incomplete mid-diastolic closure of anterior and posterior cusps was recorded. "Snowy" echoes were generally present. During diastole, high-frequency fluttering of the anterior and posterior cusps was present.

Identification of the posterior edge echoes of the posterior stent was generally difficult because of reverberations. Two-dimensional echocardiograms of the prosthesis in the aortic position (Fig. 6) showed minimal motion of the longitudinal axis of the stents. Cusp echoes were smooth and had a regular consistent motion in both the short and the longitudinal axis. The cusp thickness was 2 to 3 mm and the mean stent diameter 20 mm. Heavier echoes were observed at the junction of the interventricular septum with the aortic wall. Two-dimensional echocardiograms of the prosthesis in the mitral position showed similar characteristics of the

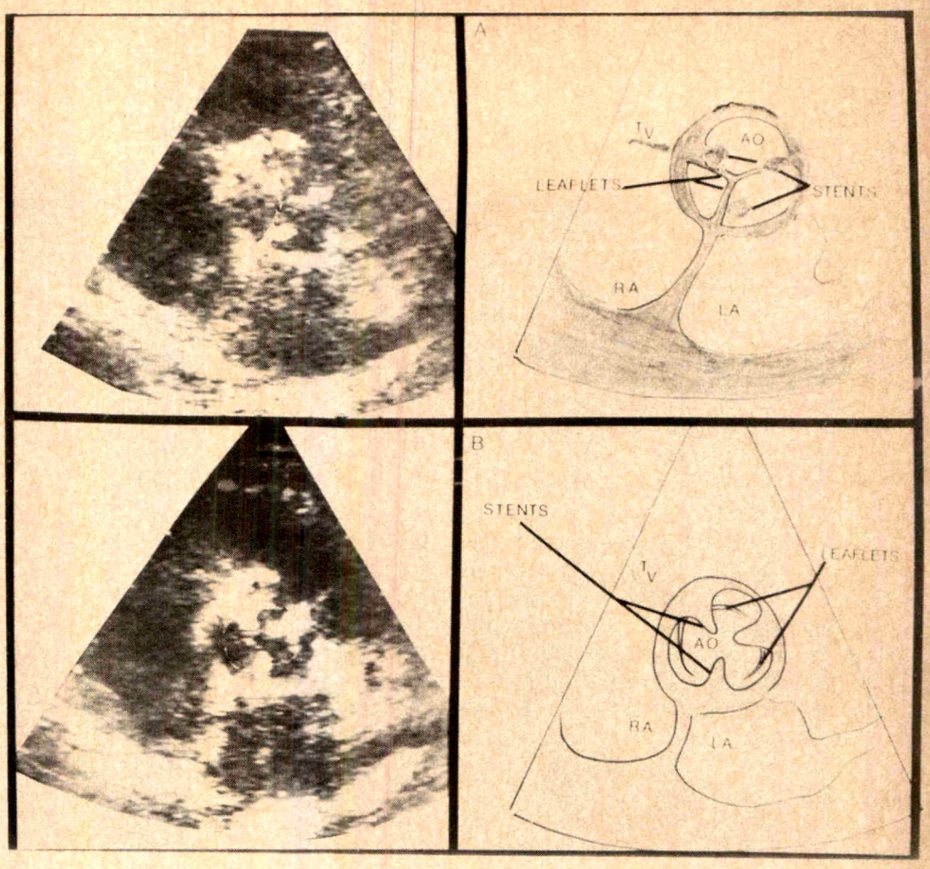

FIGURE 6. Short-axis 2-D echocardiograms of the Ionescu-Shiley prosthesis in the aortic position. **A,** valve in closed position; **B,** valve in open position. AO = aortic valve; LA = left atrium; RA = right atrium; TV = tricuspid valve.

stents, cusp motion, and thickness (Fig. 7). Heavy echoes were consistently recorded behind the posterior stent. The stent motion was concordant with motion of the ventricular posterior wall and anulus. No tilting or rocking motion was observed. Hemiaxial sector scans were also helpful in demonstrating the character of the stent echoes and cusp motion.

Discussion

This study indicates that with few exceptions, there is a reasonable approximation of manufacturer's essential dimensions and echocardiographically obtained values in subjects with the Ionescu-Shiley prosthesis.

The in vitro detachment of part of 1 cusp produced coarse fluttering of the abnormal cusp, whereas a tear in the base of 1 cusp produced occasional abnormal fluttering echoes below the affected cusp during ejection. Two-dimensional and M-mode echoes were helpful in demonstrating this abnormality. These findings agree with data of Alam et al[13] in patients with clinical porcine xenograft insufficiency. Our in vitro findings indicate that massive cusp detachment can be missed in the casual M-mode examination of this prosthesis because apparently normal echoes can be produced by changing acoustic windows and transducer angle. In such a setting, 2-D scanning of the valve disclosed the mechanical derangement. Multiaxial 2-D echocardiographic ex-

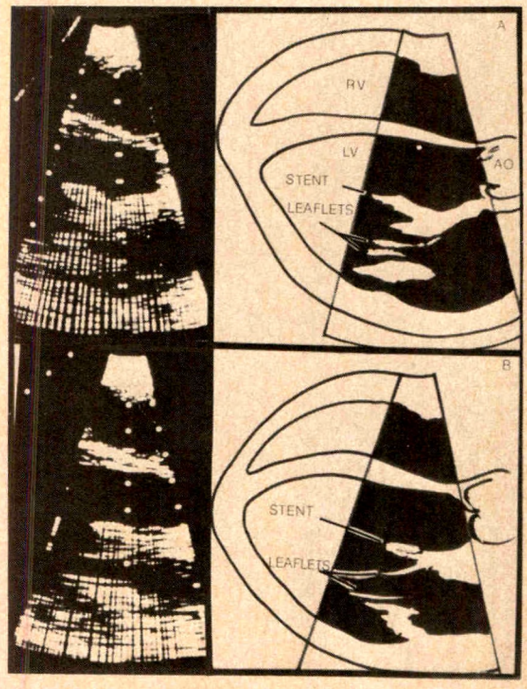

FIGURE 7. Long-axis 2-D echocardiograms of the Ionescu-Shiley mitral prosthesis. **A,** valve in closed position; **B,** valve in open position. Ao = aortic root; LV = left ventricle; RV = right ventricle.

amination of the valve using several acoustic windows is essential to evaluate the Ionescu-Shiley prosthesis. This finding accords with previous reports by Alam et al,[13] Schapira et al,[14] and Martin et al[17] regarding the superiority of 2-D sector scanning over M-mode echocardiography in the evaluation of porcine xenografts. The M-mode internal/external stent diameter has been suggested to be an index of thrombosis of the valve orifice[9] in the porcine bioprosthesis; however, technical difficulty in determining internal diameter and variations in the measurements of the external diameter[12] appear to reduce the sensitivity of these indexes. In the Ionescu-Shiley valve, we have noted variation between the measured M-mode values and the manufacturer's standard measurements. Despite these discrepancies, extreme changes in these values during the longitudinal follow-up of the individual patient will likely prove of diagnostic value. As is true for porcine xenografts, determination of external stent diameter is difficult because of reverberations behind the posterior stent, especially with the valve in the mitral position.

Two-dimensional echocardiographic determinations of cusp thickness and stent smoothness along with motion throughout the cardiac cycle are possible with the Ionescu-Shiley prosthesis in both the aortic and the mitral positions. To fully assess this prosthesis several acoustic windows in addition to the standard recording site must be employed.

Acknowledgment: We thank Lee B. Brown, MD, who performed surgery in most of the patients in the study, and Paul E. Morris of Shiley Laboratories, Inc., who provided the valve used in our in vitro study. Also, we acknowledge the technical assistance of Sydney Peebles, Ida Mack, Connie Sheasby, Carole Crevier, Jennie Goff, and Mary Throop.

Aortic Valve Systolic Flutter as a Screening Test For Severe Aortic Stenosis

MICHAEL L. CHIN, MD, ROBERT F. BERNSTEIN, MD, JOHN S. CHILD, MD, and JANINE KRIVOKAPICH, MD

Previous efforts using M-mode echocardiography or 2-dimensional (2-D) echocardiography have not consistently separated patients with and without significant aortic stenosis (AS). We postulated that an aortic valve sufficiently pliant to produce systolic flutter on M-mode echocardiography could exclude significant AS and reviewed the M-mode echocardiograms of 50 consecutive patients (mean age 59 years) catheterized for presumed AS; 2-D echocardiography was also performed in 18 of 50 patients (36%). In 40 of 50 patients (80%) the aortic valve cusps were easily identified on M-mode echocardiography: 19 of 40 (48%) had systolic flutter with a mean aortic valve gradient of 4 ± 8 mm Hg (mean ± standard deviation [SD]) and an aortic valve area of 2.8 ± 0.4 cm^2; 21 of 40 (52%) had no systolic flutter with a mean aortic valve gradient of 55 ± 19 mm Hg and an aortic valve area of 0.7 ± 0.3 cm^2. In the 10 of 50 patients (20%) in whom aortic valve cusps were not clearly identified, the mean aortic valve gradient was 50 ± 24 mm Hg and the aortic valve area 0.8 ± 0.4 cm^2. Systolic flutter was not seen with an aortic valve gradient >30 mm Hg or an aortic valve area <1 cm^2. Aortic valve systolic opening by M-mode echocardiography or 2-D echocardiography did not accurately predict the severity of AS. Thus, aortic valve systolic flutter seen on M-mode echocardiography is strong evidence against significant AS, but the absence of systolic flutter does not allow reliable prediction of the severity of AS. The finding of systolic flutter by M-mode echocardiography may be a useful screening test in patients presumed to have AS.

M-mode echocardiographic attempts to quantitate the degree of aortic stenosis (AS) have not been consistently successful.[1–8] Direct observation of aortic valve motion on 2-dimensional (2-D) echocardiography offered more promise,[9] but quantitation of the severity of AS in the individual is inaccurate.[10] Aortic valve systolic flutter (high-frequency oscillations of 1 or both aortic valve leaflets during systole) is a frequent M-mode echocardiographic finding in normal subjects.[1,2,11] Its presence in part reflects a pliable valve leaflet. We postulated that aortic valve systolic flutter would be seen only in patients with aortic valve disease who had at least 1 aortic leaflet sufficiently pliant that it would not significantly impede transvalvular flow. This study was designed to assess (1) how frequently aortic valve systolic flutter occurs in patients being evaluated for presumptive AS, (2) whether the presence or absence of systolic flutter of the aortic valve predicts the severity of AS as assessed at cardiac catheterization, and (3) how the predictive value of systolic flutter compares with the measurement of aortic valve systolic opening on 2-D echocardiography.

Methods

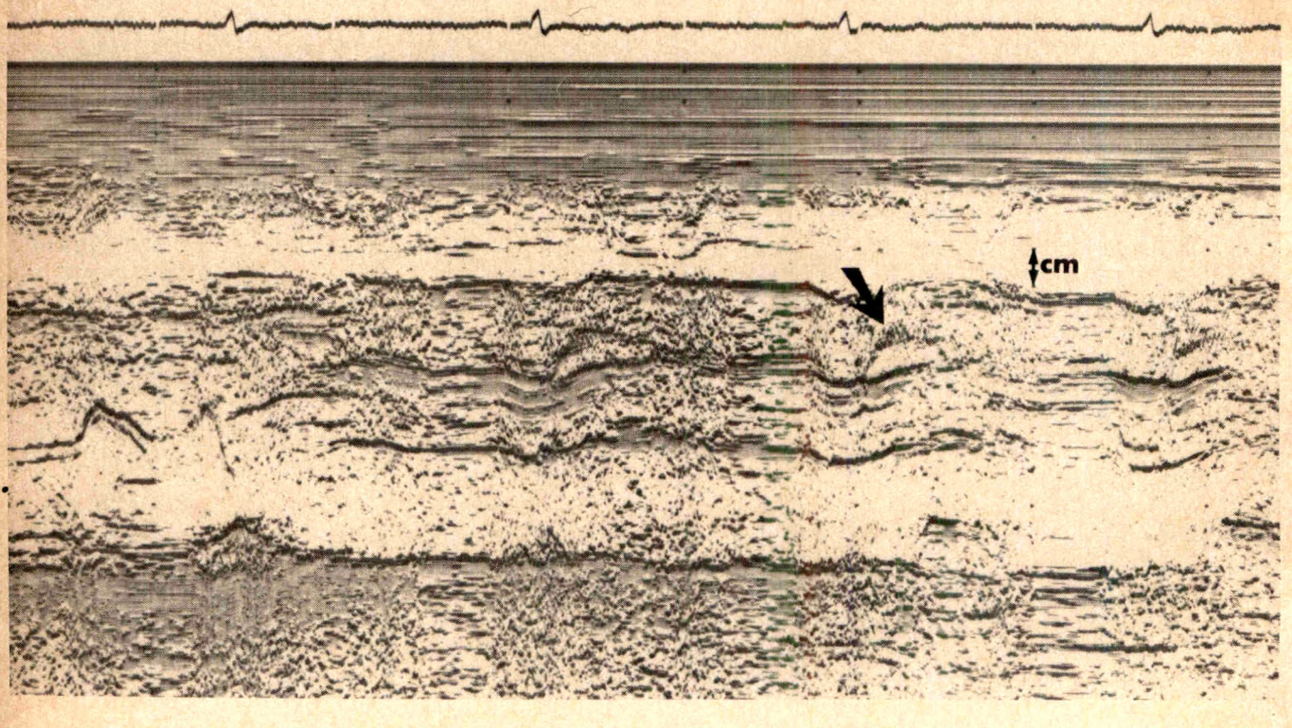
Patients: We retrospectively examined the records of all patients who underwent cardiac catheterization for evaluation of AS between January 1, 1978 and December 31, 1981 who also had M-mode echocardiography performed within 48 hours of catheterization. We excluded 4 patients, 3 because of the lack of adequate hemodynamic data and 1 because of the presence of subvalvular aortic obstruction. The resultant study group included 50 patients.

Cardiac catheterization: Right and left heart catheterization was performed in the standard manner. Aortic valve gradients were determined by simultaneous left ventricular and brachial artery pressure during retrograde left ventricular catheterization or simultaneous left ventricular and aortic pressure during transseptal catheterization. Hemodynamic data and measurements of cardiac output by the Fick method were used to derive the mean aortic valve gradient and to es-

timate the aortic valve area using the modified Gorlin formula.[12] For purposes of statistical analysis, aortic valve area was considered to be 3.0 cm^2 (normal) when the aortic valve gradient was 0,[13] because the Gorlin formula is not applicable in this situation.[12]

Echocardiography: M-mode echocardiography using a Smith-Kline Ekoline 20 recorder with a 2.25 MHz transducer and a Honeywell model 1856A fiberoptic strip chart recorder was performed using standard technique.[14] Three independent observers, with no knowledge of patient identity or the results of cardiac catheterization and 2-D echocardiography, reviewed the M-mode echocardiograms for the presence of aortic valve systolic flutter. All observers had to be in agreement for purposes of this study. Patients in whom the aortic valve leaflet could not be clearly identified were placed in the subgroup designated "Cannot Evaluate." Figure 1 shows a typical M-mode echocardiogram in an adult being evaluated for possible AS. Despite the presence of numerous dense echoes in the aortic root, at least 1 aortic leaflet can be identified and the presence of aortic valve systolic flutter is easily identified.

Two-dimensional echocardiograms were performed with an SKI Ekosector 20A system with a 30° mechanical sector scanner and a Sanyo 1/2 inch video recorder or a Toshiba SSL-53M Sonolayer V with 80° electronically phased array transducer and a Sony 1/2 inch video recorder. Standard parasternal long- and short-axis and apical 4-chamber views were obtained.[15] Two-dimensional echocardiography performed at the same time as M-mode echocardiography was available in 18 of 50 patients. In 3 of these patients, 2-D echocardiograms were technically inadequate and were excluded. The remaining 15 patients included 8 women and 7 men with a mean age of 57 years (range 22 to 78). These 2-D echocardiograms were reviewed by 3 independent observers



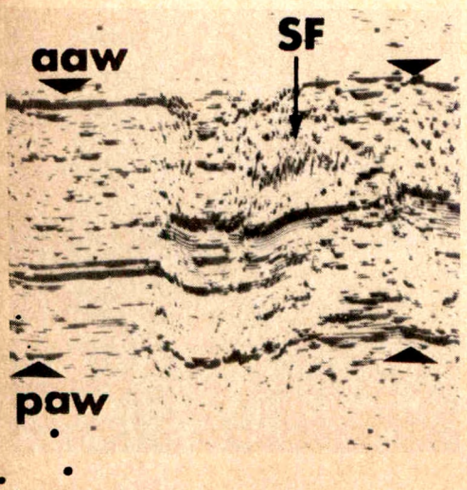


FIGURE 1. M-mode echocardiogram of aortic valve systolic flutter in a patient with no aortic valve gradient. **Top,** standard sweep from mitral valve (**left**) to aortic root. (unaware of patient identity and the results of cardiac catherization and M-mode echocardiography) for the presence or absence of aortic valve systolic flutter in long-axis views and for maximal aortic valve leaflet separation in long- and short-axis views (Fig. 2 and 3).

Results

Complete hemodynamic records and M-mode echocardiograms were available for analysis in 50 patients. The study population was partitioned into 3 groups (Table I) according to the appearance of the aortic valve leaflets on M-mode echocardiography; the valve leaflets could not be identified by the 3 reviewers in 10 of 50 patients because of multiple linear echoes in the aortic root. These extraneous echoes are probably due to calcification or fibrosis of the aortic root wall or valve leaflets. Because the true echoes generated by the free edges of the valve leaflets could not be identified in these patients, they were grouped separately (Group I). The remaining 40 patients were divided into 21 patients (52%) without aortic valve systolic flutter (Group II) and 19 patients (48%) who demonstrated aortic valve systolic flutter (Group III). The 3 groups are summarized in Table I.

TABLE I Characteristics of Patient Population

	Group I (n = 10)	Group II (n = 21)	Group III (n = 19)
Mean age (yr)	56	61	49
Males	5	13	7
Females	5	8	12
Mitral stenosis	1	3	8
Mitral regurgitation	2	11	10
Aortic regurgitation	5	16	10
Aortic valve gradient (mm Hg)	50 ± 24	55 ± 19	4 ± 8
Aortic valve area (cm^2)	0.8 ± 0.4	0.7 ± 0.3	2.8 ± 0.4

M-mode echocardiography: The aortic valve gradient and the aortic valve area (mean ± SD) in Groups I and II were similar (Table I). Patients in Group III demonstrated a lower average aortic valve gradient and a larger aortic valve area than did patients in Groups I and II ($p < 0.001$).

Data were stratified according to those with and those without significant AS (for purposes of statistical analysis, mean aortic valve gradient was ≥30 mm Hg and calculated aortic valve area was ≤1.0 cm^2). Of 31 patients without systolic flutter (Groups I and II), 26 (84%) had an aortic valve gradient ≥30 mm Hg and 28 (90%) had an aortic valve area ≤1.0 cm^2. In Group III, only 1 patient (5%) had an aortic valve gradient equal to 30 mm Hg; none had a gradient >30 mm Hg or aortic valve area ≤1.0 cm^2 (Table II).

In the 40 patients in whom aortic leaflets could be clearly identified by M-mode echocardiography (Groups II and III), the *accuracy* ([true-positive + true-negative] ÷ [total number of tests]) of aortic valve systolic flutter in excluding hemodynamically significant AS was 95%. If aortic valve systolic flutter was present, the *predictive value* ([true-positive] ÷ [true-positive + false-negative]) of this finding in identifying patients without hemodynamically significant AS was 95%.

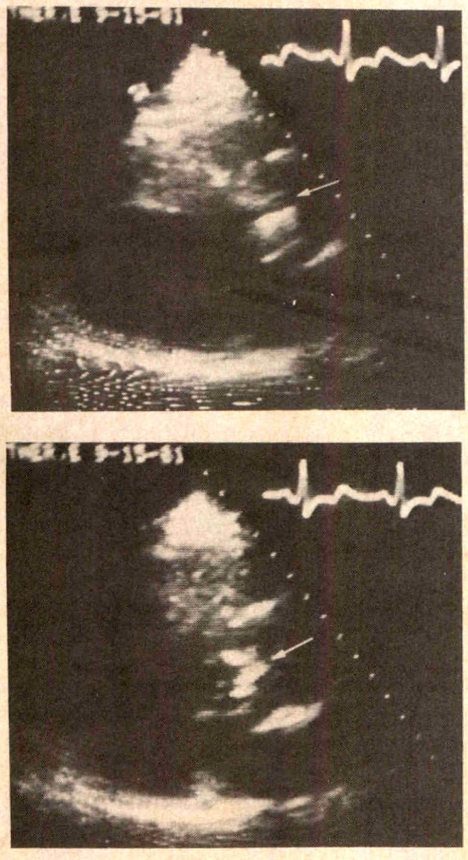

FIGURE 2. Parasternal long-axis 2-D echocardiogram of patient in Figure 1 with no aortic valve gradient. **Top,** maximal systolic opening of aortic valve (**arrow**) is 5 to 6 mm. Frame is at low gain in order to visualize leaflet separation on the heavily calcified aortic valve. **Bottom,** diastolic closure of the same heavily calcified aortic valve.

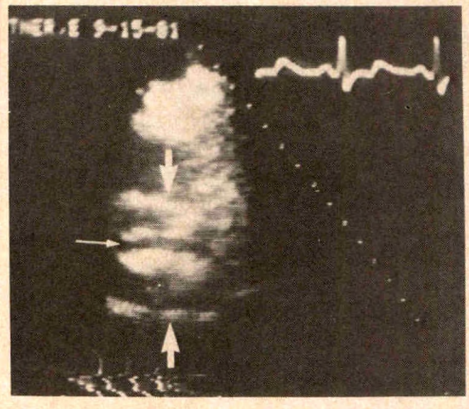

FIGURE 3. Parasternal short-axis 2-dimensional echocardiogram of the aortic valve in the patient in Figure 2. Maximal anteroposterior systolic separation (**small arrow**) of the heavily calcified aortic valve is 5 mm. **Large arrows** indicate anterior and posterior walls of the aortic root.

TABLE II Two by Two Contingency Tables Relating the Severity of Aortic Stenosis to the Presence or Absence of Aortic Valve Systolic Flutter in Group II and III Patients

	Systolic Flutter	
	+	−
Aortic valve area		
≤ 1.0 cm^2	0	19
>1.0 cm^2	19	2
	$\chi^2 = 32.74$; $p < 0.0001$	
Aortic valve gradient		
≥ 30 mm Hg	1	19
<30 mm Hg	18	2
	$\chi^2 = 28.97$; $p < 0.0001$	

Two-dimensional echocardiography: Two-dimensional echocardiograms, available for review in 18 patients, were technically adequate for evaluation of the aortic valve in 15 patients. The aortic valve area was >1.0 cm^2 in 7 patients, but aortic valve systolic flutter was noted on the 2-D echocardiogram in only 1 patient (14%). In contrast, M-mode echocardiography showed systolic flutter in 6 of these 7 patients. Aortic valve systolic opening estimated by 2-D echocardiography only generally corresponded with the aortic valve area obtained by catheterization and was not as accurate in allowing stratification of patients as was the presence of aortic valve systolic flutter on M-mode echocardiography. The aortic valve systolic opening on 2-D echocardiography measured 12 ± 5 mm (range 6 to 18) in patients with a valve area >1.0 cm^2 and was 8 ± 4 mm (range 5 to 14) in patients with a valve area ≤ 1.0 cm^2.

Discussion

Our study demonstrates that at least 1 aortic valve leaflet is identifiable on M-mode echocardiography in 80% of adults with suspected AS. Clear visualization of high-frequency systolic flutter on an aortic leaflet reliably excluded hemodynamically significant AS. No patient with aortic valve systolic flutter on M-mode echocardiography had an aortic valve area <1.0 cm^2 or an aortic valve mean gradient >30 mm Hg at cardiac catheterization.

We defined the hemodynamic severity of AS by the Gorlin formula,[12] which required a measured transvalvular gradient and forward transvalvular flow to calculate the aortic valve orifice area. For this study, we selected a gradient (mean) of ≥ 30 mm Hg and an aortic valve area ≤ 1.0 cm^2 as hemodynamic evidence of "significant" or severe AS. With aortic regurgitation, the Fick cardiac output underestimates the aortic transvalvular forward flow. Thus, *calculated* aortic valve orifice area would represent the minimum; *actual* aortic valve area may be larger. This finding does not decrease the value of the *presence* of aortic valve systolic flutter in excluding severe AS. At least 50% of patients in each group had angiographic evidence of aortic regurgitation, making it unlikely that the presence or absence of aortic regurgitation plays a predominant role in the production of aortic valve systolic flutter. Because of the sizable minority (20%) of patients in whom aortic valve leaflets were not easily identifiable, the absence of systolic flutter cannot reliably be used to diagnose significant AS. Because of the high-frequency systolic flutter, the small amplitude oscillations, and the lower sampling rate of 2-D echocardiography, it is no surprise that 2-D echocardiography (even with a high-resolution, narrow angle sector scanner) was not as sensitive as M-mode echocardiography in identifying aortic valve systolic flutter. The true systolic separation of the aortic leaflets on 2-D echocardiography was often obscured by echoes reverberating from calcification or thickening of the aortic root or valve in both the long- and short-axis parasternal views. Thus, 2-D echocardiography was of limited usefulness in stratifying patients with and without significant AS.

Clinical assessment of the severity of aortic valvular obstruction in adults with presumed AS can be difficult. Patients may have significant obstruction with few or no symptoms, and in the presence of advanced age, systemic hypertension, or left ventricular dysfunction, the physical signs of severe AS can be misleading.[16–18]

Correlation of a number of M-mode echocardiographic features of aortic valve disease such as aortic leaflet thickening, extraneous aortic root echoes, or reduced aortic valve leaflet separation, and the hemodynamic severity of AS have met with limited success.[1–5] An empiric wall stress constant derived from M-mode measurements of left ventricular dimensions and wall thickness has been useful in predicting the degree of AS in children and in some adults. Technical limitations or the presence of systemic hypertension, left ventricular dysfunction, or aortic insufficiency renders this method inapplicable in many adults.[6–8]

With superior spatial representation, 2-D echocardiographic direct measurement of aortic valve orifice areas seemed possible.[9] As in our study, further investigation has revealed the inaccuracy of this method.[10] Pulsed Doppler echocardiography, by examining blood flow characteristics in the ascending aorta, has reportedly been useful in screening patients for possible severe AS.[19] This method may not be applicable when transvalvular flow is significantly altered, as in aortic regurgitation or low cardiac output. Proper interpretation of the pulsed Doppler record in AS requires methodical examination and knowledge of the flow system beyond the stenotic valve.[20] More promising, continuous wave Doppler can be used to record the maximal velocity of the stenotic jet to estimate the pressure gradient, using the Bernoulli equation.[21]

In our laboratory, physicians frequently request an echocardiogram to evaluate the cause of a systolic murmur. The referred patients often have nonspecific findings on history and physical examination. Electrocardiographic abnormalities such as voltage criteria for left ventricular hypertrophy are frequent, but their significance is unclear because many of these patients have a history of systemic hypertension. Many patients will demonstrate increased echoes in the aortic root on M-mode echocardiography, which are not specific for aortic valvular obstruction. The echocardiographer is

obligated to interpret such tracings as being consistent with either aortic stenosis or sclerosis. By searching for aortic valve systolic flutter, a more accurate estimation of the likelihood of significant AS can be made. Simple detection of aortic valve systolic flutter makes severe AS unlikely and should be clinically useful in the decision-making process regarding the need for cardiac catheterization. Conversely, the absence of aortic valve systolic flutter does not necessarily indicate significant AS.

Detection and Estimation of Rheumatic Mitral Regurgitation In the Presence of Mitral Stenosis by Pulsed Doppler Echocardiography

ASHVIN K. PATEL, MD, GEORGE G. ROWE, MD, JAMES H. THOMSEN, MD, SHIRAZ P. DHANANI, MD, PETER KOSOLCHAROEN, MD, and LOU ELLEN W. LYLE, BS

The sensitivity and specificity of pulsed Doppler echocardiography (PDE) in diagnosis and estimation of the severity of mitral regurgitation in the presence of rheumatic mitral stenosis was studied in 34 patients (18 women and 16 men) ranging in age from 33 to 70 years (mean 55). Definitive diagnosis of mitral regurgitation was confirmed in all patients by angiography and in 20 patients also by indicator dilution technique. Mitral regurgitation was detected by PDE in all patients with angiographically proven severe mitral regurgitation and in 7 of 8 patients with moderate mitral regurgitation. In patients with trace to mild mitral regurgitation, PDE was positive in only 7 of 13 patients. When subdivided for mild, moderate and severe mitral regurgitation, PDE sensitivity for diagnosis was 54, 88, and 100%, respectively; overall accuracy was 79% and specificity was 100%.

Average systolic dispersion on time-interval histogram was 59% for mild, 89% for moderate, and 100% for severe mitral regurgitation. Groups of patients with mild mitral regurgitation could be differentiated from those with moderate ($p < 0.05$) and severe ($p < 0.01$) mitral regurgitation. A significant overlap of individual values, however, occurred. In 7 of 11 patients with moderate to severe mitral regurgitation, systolic turbulence also was detected in the left atrium. PDE was sensitive and specific in diagnosing moderate to severe mitral regurgitation in the presence of mitral stenosis. Assessment of precise severity of mitral regurgitation is still a problem in individual patients.

M-mode and 2-dimensional echocardiography are useful noninvasive techniques in the diagnosis and assessment of severity of rheumatic mitral stenosis.[1–3] These techniques, however, provide little direct information about associated mitral regurgitation. Since there is an increasing trend among cardiologists to subject patients with mitral stenosis and other valvular heart disease to cardiac surgery[4–6] based on clinical and echocardiographic evaluation without doing cardiac catheterization, additional information about associated regurgitation could be helpful in deciding preoperatively whether a patient should undergo mitral valve repair or replacement. Range-gated pulsed Doppler echocardiography (PDE) noninvasively identifies blood flow patterns at well-defined locations in the heart and detects stenotic or regurgitant lesions.[7] In this study, the sensitivity and specificity of PDE in diagnosing and estimating the severity of mitral regurgitation in the presence of mitral stenosis was examined.

Methods

Thirty-four patients (18 women and 16 men) with mitral stenosis, ranging in age from 33 to 70 years, were studied by PDE between January 1978 and December 1981. The severity of mitral regurgitation was assessed clinically by an attending cardiologist based on characteristics of the left ventricle and systolic murmur. Most of these patients were studied by PDE within 48 hours of cardiac catheterization. PDE was performed in all patients by a technician who was unaware of clinical or angiographic diagnosis. Eighteen healthy medical students in whom organic heart disease was excluded by usual clinical means served as control subjects.

Cardiac catheterization: The severity of mitral stenosis was estimated by measuring the mean diastolic gradient across the mitral valve from simultaneously recorded pulmonary artery wedge or left atrial pressure and the left ventricular

diastolic pressure tracings, and by calculating mitral valve orifice using Gorlin's formula. Mitral stenosis was considered mild when the mitral valve orifice was 1.5 to 2.5 cm^2, moderate when it was 1.0 to 1.5 cm^2, and severe when it was <1 cm^2. Mitral regurgitation was assessed from the amount of opacification of the left atrium by contrast material after left ventriculography. It was classified as mild if there was minimal staining of the left atrium which cleared rapidly, moderate if the left atrium was opacified with slow clearing, and severe if complete opacification of the left atrium occurred with the first cycle and continued throughout the entire period of ventriculography.

Mitral regurgitation was further confirmed in 20 patients by indicator-dilution curves. A catheter (size 8 rattail) was placed in the left ventricle. The transseptal catheter was placed in the left atrium above the mitral valve. Indocyanine green dye (0.06 mg/kg) was flushed carefully with 6 ml of saline solution through the catheter in the left ventricle. Sampling from the left atrium and femoral artery was done through cuvette densitometers with constant withdrawal syringes (Harvard Apparatus, Millis, Massachusetts). A Hewlett-Packard recorder was used to record dye curves. Depending on the time of appearance, the amount of dye in the left atrium, and configuration of the dye curves, mitral regurgitation was graded as mild, moderate, or severe.[8,9]

Doppler echocardiography: Initially we studied 12 patients and 9 medical students using an ATL (Advanced Technology Laboratories, Bellevue, Washington) 500A pulsed Doppler echocardiograph with a Honeywell 1856 ultraviolet recorder. This instrument employs a single 3 MHz piezoelectric transducer, 0.5 inch in diameter and focused at 5 cm, which operates simultaneously for both Doppler and echocardiographic procedure (M-mode PDE). We studied the remaining 22 patients since August 1979 using the Mark V ATL system which provides real-time images of cardiac structures, which can be frozen to allow investigation of blood flow by 2-dimensional PDE. The frozen-section image has a superimposed radial line with a bright spot (Doppler sample volume). The operator can move the line radially across the image and adjust depth of the sampling site by moving the bright spot along the line to an appropriate position.

In both systems, flow can be detected in a teardrop-shaped region approximately 2 mm in diameter and 4 mm in length at any depth from 2 to 15 cm along the ultrasonic beam. Two types of output are available from this device. The first is an audio signal (400 Hz to 5 kHz) that corresponds to the spectrum of Doppler shifts produced by normal or disturbed blood flow and allows interpretation based on tonal quality. The second is an on-line graphical display of the Doppler shift frequencies (time-interval histogram [TIH]) which is printed on a strip-chart recorder. Laminar blood flow produces a narrowly clustered dot pattern (narrow-band pattern) because reflected sound waves have a fairly uniform Doppler shift. Turbulent flow produces a widely dispersed dot pattern (wide-band pattern) because blood cells have varied direction and velocity. Principles and use of TIH are described in detail by Lorch et al.[10]

With the patient in supine or left lateral position, the mitral valve was located and the M-mode PDE transducer was oriented so that the ultrasonic beam was almost parallel to the axis of flow to insure maximal blood flows. Mitral valve, intermediate area, anulus, and the left atrium were carefully explored for mitral stenosis and regurgitation.

In patients studied by 2-dimensional PDE, blood flow information was also obtained from similar mitral valve areas. Since 2-dimensional echocardiography has better spatial resolution than M-mode, it was possible to sample blood flow velocities in long-axis, short-axis and 4-chamber apical views.

The threshold control was adjusted to eliminate most background noise. The Doppler gain was adjusted so that the input signal presented as peaks, off the baseline. The audio signal and the frozen 2-dimensional image of the mitral valve, with superimposed line delineating position of the Doppler sample volume, were recorded on a video cassette recorder (Sanyo model VTC 7100); TIH was printed on a fiber optic

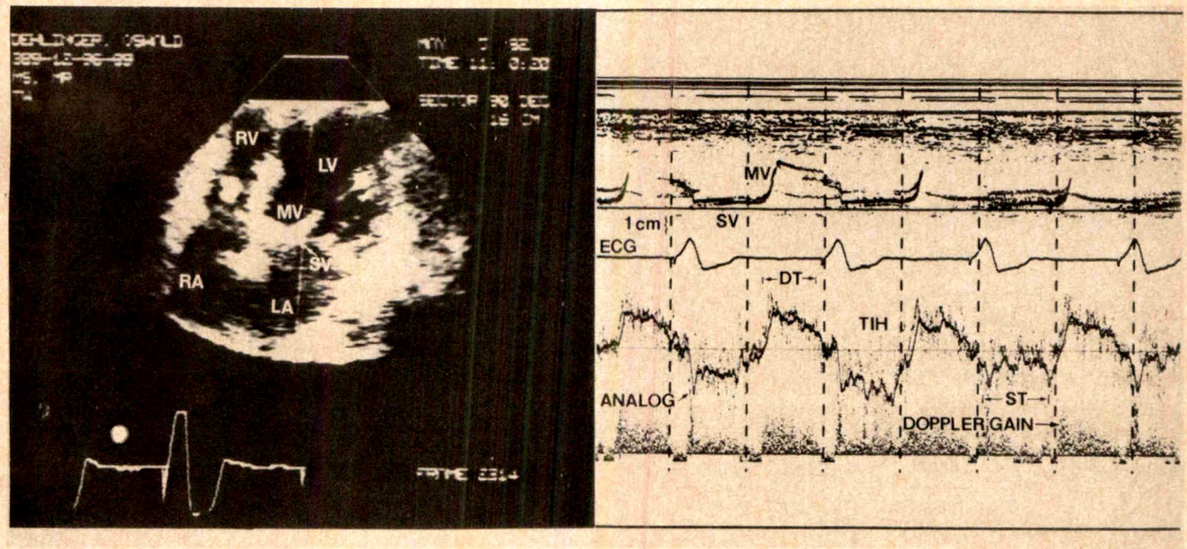

FIGURE 1. Pulsed Doppler echocardiographic examination over left ventricular inflow region from apical 4-chamber view. The **left panel** shows a continuous line with a dot indicating the position of the sample volume (SV). The **right panel** indicates the position of the SV on M-mode echocardiogram (upper half) and time-interval histogram (TIH) (lower half). Note the turbulent (wide scattering of dots) diastolic flow indicating mitral stenosis and the negative turbulent flow in systole indicating mitral regurgitation. The superimposed analog flow signal shows a serrated, uneven pattern. DT = diastolic turbulence; LA = left atrium; LV = left ventricle; MV = mitral valve; RA = right atrium; RV = right ventricle; ST = systolic turbulence.

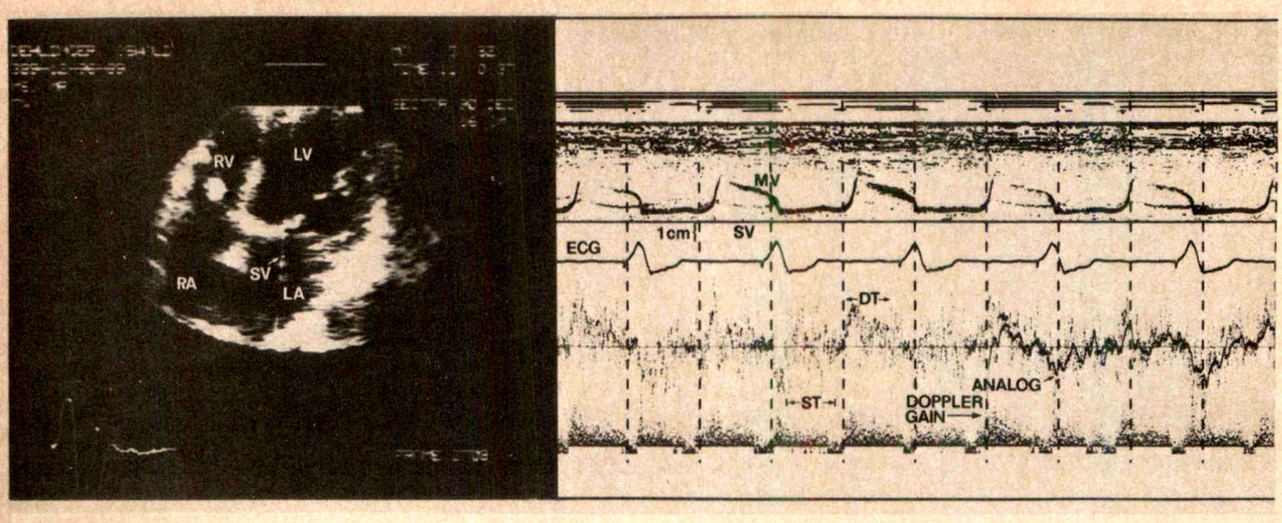

FIGURE 2. Pulsed Doppler examination of the same patient with sample volume placed deeper in the left atrium. Diastolic and systolic turbulence is again noted, although forward and reverse direction of blood flow is not as striking compared with sampling over left ventricular inflow region. Abbreviations as in Figure 1.

recorder at a paper speed of 25 to 40 mm/s. An analog flow velocity curve which represents an average of Doppler shift frequencies was also superimposed on the TIH. Detection of turbulent flow confirmed the diagnosis of mitral stenosis when present in diastole, and mitral regurgitation when in systole. The width and configuration of special dispersion on TIH from 5 consecutive cycles were analyzed in all patients. For mitral regurgitation, the ratio of maximal systolic dispersion on TIH to total duration of systole was calculated (Fig. 1). The systolic dispersion on TIH was divided into 3 segments corresponding to mild (<50%), moderate (50 to 75%), and severe (>75%) turbulence. A relation between amplitude, width, and breadth of negative wave on analogue and severity of mitral regurgitation has been noted by Kalmanson et al.[11] Severity of mitral regurgitation was also assessed by tracing the systolic turbulence from mitral leaflets to the left atrium (Fig. 2).[12,13]

Results

Cardiac catheterization data: The average diastolic gradient and calculated mitral valve orifice size in 33 patients is summarized in Table I. A majority of the patients had moderate to severe mitral stenosis. In 2 patients with predominant mitral regurgitation, only an early diastolic gradient was noted. In 1 patient with severe mitral stenosis and a large left atrial thrombus partially blocking the pulmonary veins, pulmonary artery wedge pressure could not be obtained.

Correlation was good between the clinical diagnosis of the presence of mitral regurgitation and diagnosis by the angiographic or dye-dilution method, as illustrated by Figure 3. However, 4 false-positive diagnoses were

TABLE I Distribution of 33 Patients With Mitral Stenosis According to Average Mitral Valve Orifice Size and Diastolic Pressure Gradient

Mitral Stenosis	Mild	Moderate	Severe
Mitral valve orifice (cm^2)	>1.5	1.0–1.5	<1.0
Diastolic pressure gradient (mm Hg)	<10	10–20	>20
Average mitral valve orifice size	2.64 (8)*	1.25 (11)	0.76 (14)
Average diastolic pressure gradient	6.7 (8)	15.4 (17)	26.8 (8)

* Number in parentheses indicates number of patients.

TABLE II Angiographic and Doppler Correlation of Mitral Regurgitation

Mitral Regurgitation	Angiography	Doppler				
		Negative	Positive	% TIH		
None	9	9	0	0		
Mild	13	6	7	59	$p < 0.05$	$p < 0.01$
Moderate	8	1	7	88		
Severe	4	0	4	100	$p > 0.02$	
Total	34	16	18			

TIH = average percent systolic turbulence.

made clinically, while none was documented during cardiac catheterization. There was also considerable disparity between clinical and angiographic assessments of the severity of mitral regurgitation. While severe cases of mitral regurgitation correlated well by both methods, there was significant disparity in mild and moderate cases. A significant disparity was also noted between clinical and PDE assessment of presence and severity of mitral regurgitation (Fig. 4).

Doppler data: *Normal subjects:* The spectral pattern for diastolic flow across the normal mitral valve mimicked the motion of the anterior leaflet echogram of the mitral valve. Nonturbulent, anteriorly directed flow was found to commence with the opening of the mitral valve in all patients. This flow diminished until late diastole, when a second peak occurred with atrial contraction. The early and late diastolic flows were separated in mid-diastole by what appeared to be a period of virtually no detectable flow or by an intermediary peak. During isometric contraction of the left ventricle, a brief negative deflection was seen in most subjects. Systolic turbulence, by audio signal or TIH, was not detected in any of the normal subjects.

Mitral stenosis: Abnormal diastolic turbulence was noted in all except 2 patients—1 with severe and the other with mild mitral stenosis. Overall sensitivity in diagnosis of mitral stenosis was 94%. There was no correlation between severity of mitral stenosis and type of blood flow patterns obtained on TIH.

Mitral regurgitation: Pulsed Doppler echocardiography did not detect any mitral regurgitation in the control group of 18 healthy medical students or in 9 patients with pure mitral stenosis without mitral regurgitation on ventriculography or dye-dilution curves. Therefore, overall specificity was 100%.

Mitral regurgitation was detected by PDE in all patients with angiographically proven severe mitral regurgitation and in 7 of 8 patients with moderate mitral regurgitation. In patients with trace to mild mitral regurgitation, however, PDE was positive in only 7 of 13 patients (Table II). Overall sensitivity in detecting mitral regurgitation for all patients was 72%. When subdivided for mild, moderate, and severe mitral regurgitation, PDE sensitivity for diagnosis was 54, 88, and 100%, respectively. Overall accuracy was 79% and specificity was 100%.

Average systolic dispersion on TIH was 59% for mild, 88% for moderate, and 100% for severe mitral regurgitation. Groups of patients with mild mitral regurgitation could be distinguished from those with moderate ($p < 0.05$) and severe ($p < 0.01$) mitral regurgitation; however, there was considerable individual overlap and the latter 2 groups could not be separated based on TIH alone.

Severity of mitral regurgitation was also assessed by tracing systolic turbulence from mitral valve to the left atrium. In 7 out of 11 patients with moderate to severe mitral regurgitation systolic turbulence was detected in the left atrium. Only 1 patient with mild mitral regurgitation had detectable systolic turbulence in the left atrium.

PDE was therefore both sensitive and specific in diagnosing moderate to severe mitral regurgitation in the presence of mitral stenosis. Overall correlation between PDE and angiography in the diagnosis of trace to mild mitral regurgitation was poor. Assessment of severity of mitral regurgitation by time-interval histogram, in individual patients, is still a problem.

Discussion

Evaluation of mitral regurgitation is difficult by any presently accepted method; therefore, any new method must be examined carefully. Traditionally, the surgeon evaluated mitral regurgitation at operation by palpating the regurgitation jet which came through the valve into

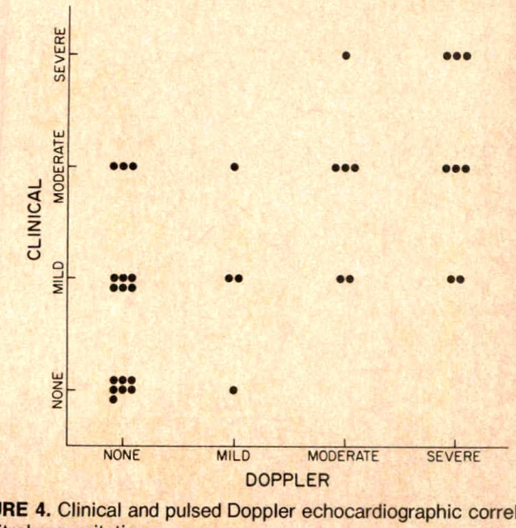

FIGURE 4. Clinical and pulsed Doppler echocardiographic correlation of mitral regurgitation.

the left atrium during systole. Unfortunately, this method is not reliable because it depends on the force of left ventricular contraction, systolic and left atrial blood pressure, and the size of the regurgitant orifice. This technique is still used and is usually part of the clinical decision concerning valve replacement. The catheterization technique, which depended on the contour of the left atrial pressure and the height of the V wave, quickly fell into disrepute because of significant discrepancies.[14] The angiographic method also has known errors created by premature contractions, arrhythmias, diastolic regurgitation, distortion of valve closure by the catheter, and the problems created by inadequate mixing of blood and contrast material in the ventricle. If a small amount of regurgitated blood contains a high concentration of contrast material, regurgitation will appear to be greater than if little or no contrast material enters the atrium with regurgitated blood. Hence estimations of insufficiency are highly dependent on the position of the cardiac catheter, as well as the rate and timing of contrast injection. However, this method is the most widely employed means of assesing mitral regurgitation. Mitral regurgitation can also be quantified by comparing angiographic left ventricular stroke volume and the effective or forward stroke volume by Fick or indicator-dilution methods.[15] M-mode echocardiography, a noninvasive technique, is useful in diagnosing the cause of mitral regurgitation, but the hemodynamic abnormality is assessed by secondary and nonspecific features such as the size of the left atrium, the pulsations of the left atrial wall, the size of the left ventricle, and the pattern of interventricular septal motion.[16,17] In rheumatic mitral valve disease, echocardiographic features of mitral stenosis are dominant and mitral regurgitation may not be detected. Occasionally, in predominant rheumatic mitral regurgitation there is so-called ski sloping with an initial brisk downward E to F slope of anterior mitral leaflet with a subsequent flatter slope during the later portion of diastole.[18] This echocardiographic sign is occasionally useful but not totally reliable. On the 2-dimensional echocardiogram left atrial volume overload may be seen in severe mitral regurgitation.[19] The regurgitant mitral orifice may be recorded in patients with rheumatic mitral regurgitation.[20] However, this observation has not been confirmed by other investigators. Therefore, there is considerable interest in the recently introduced PDE technique which delineates blood flow patterns at well-defined cardiac locations.

Since Johnson et al[21] originally reported detection of mitral regurgitation by PDE, a number of reports have appeared confirming reliability of the technique.[11–13,22] Abbasi et al[12] found a specificity of 96% and a sensitivity of 92% in detection of mitral regurgitation. Of 23 patients with mitral regurgitation, 8 had rheumatic mitral disease and all were diagnosed by PDE. Abbasi et al also found a high correlation between severity of mitral regurgitation assessed by contrast ventriculography compared with PDE ($r = 0.88$; $p < 0.01$ by Pearson method). Our study also shows that PDE is sensitive in diagnosis of moderate and severe mitral regurgitation associated with varying degrees of mitral stenosis. There was only 1 false-negative result in the group with moderate mitral regurgitation. This patient had severe mitral stenosis and aortic regurgitation with a low cardiac output (cardiac index 1.241 liters/m^2). Therefore, turbulence created by mitral regurgitation may not have been severe enough to be detected by PDE. The sensitivity of PDE in diagnosis of mild mitral regurgitation was low, with only 7 out of 13 cases diagnosed. Because the sample volume is small, fixed, and single, it is possible to miss a localized jet of regurgitation in spite of careful exploration. The sensitivity of the PDE in the diagnosis of mild mitral regurgitation might have been higher if the examination had been done with the knowledge of the presence of mild mitral regurgitation on clinical evaluation and a systolic turbulence searched for more judiciously. The results of our PDE study indicate an excellent correlation in detection of moderate and severe mitral regurgitation associated with mitral stenosis. Although the degree of systolic turbulence on TIH and radiation to left atrium provides reasonably objective criteria for assessment of severity of mitral regurgitation, a significant overlap of individual values between groups is a limiting factor in the use of this technique to quantify the degree of mitral regurgitation.

Limitations of the study: Although the PDE diagnosis of mitral regurgitation was based on interpretation of TIH, the technical skill of the operator remains an important factor in obtaining an accurate study. TIH is dependent on threshold and Doppler gain settings which have to be constantly adjusted; otherwise, electronic "noise" inherent in the instrument may cause wide-dot or turbulent pattern even when blood flow is normal. The operator must be able to decipher the audio signal, explore blood flows from mitral valve at different angles to detect maximal flows, and trace the regurgitant jet to the left atrium to define an area of distribution of turbulent flow.

Because the PDE system used in our study has a single gate and a fixed sample volume, a localized jet of turbulent flow may be missed, as was evident in 6 of 13 patients with mild mitral regurgitation. It is also difficult to map the area of turbulent flow precisely. A newer instrument with a multigated system[23] and the ability to change Doppler sample volume[24] and color-coded Doppler visualization of flow[25,26] may substantially improve overall sensitivity in diagnosing and assessing severity of lesions.

Since TIH is a zero-crossing detector and does not accurately reflect the true Doppler shift frequencies, precise quantification of blood flow velocities or volume flow is not possible. To quantify volume flow, one must know true Doppler shift, valve orifice size, and the angle at which Doppler shift is obtained. With 2-dimensional echocardiography, it is possible to obtain valve orifice size and, with newer digital technology, true Doppler shift frequencies. Precise delineation of sampling angle remains a problem.

Clinical implications: Mitral regurgitation is frequently associated with mitral stenosis because of loss of valve substance, rigidity of leaflets, and shortening of chordae tendinae, all of which do not allow the mitral

valve to coapt properly in systole. Depending upon the degree of distortion of valvular and subvalvular structures, hemodynamic abnormality of mitral regurgitation varies and is of clinical importance in moderate and severe cases. Combined mitral stenosis and mitral regurgitation produce symptoms early, result in more severe pulmonary hypertension because of both pressure and volume overload, and have greater susceptibility to both bacterial endocarditis and left ventricular dysfunction. Therefore it is beneficial to assess correctly each possible lesion by combined 2-dimensional PDE.

Surgical management of patients with predominant mitral stenosis differs from that of patients with mitral regurgitation. In pure mitral stenosis, with pliable leaflets, commissurotomy is the treatment of choice, whereas with associated moderate or severe mitral regurgitation the valve needs to be replaced. There is an increasing tendency to subject patients with mitral stenosis to surgery based on echocardiographic findings without prior cardiac catheterization. Since information regarding mitral regurgitation is indirect and often not present on M-mode or 2-dimensional echocardiography, Doppler information could be helpful in deciding preoperatively whether a patient should undergo commissurotomy or mitral valve replacement.

Clinical and Echocardiographic Characteristics of Patients With Mitral Anular Calcification

Comparison With Age- and Sex-Matched Control Subjects

CHANDRA K. NAIR, MD, WILBERT S. ARONOW, MD, MICHAEL H. SKETCH, MD, SYED M. MOHIUDDIN, MD, TOM PAGANO, MD, DENNIS J. ESTERBROOKS, MD, and TOM T. HEE, MD

The clinical and echocardiographic features of 104 patients (53 women and 51 men) with mitral anular calcification (MAC) were compared with those of 121 age- and sex-matched control subjects (62 women and 59 men) without MAC. The incidence of coronary artery disease, rheumatic heart disease, systemic hypertension, and diabetes mellitus was similar in both groups. Patients with MAC had a greater incidence of cardiomegaly ($p < 0.001$), cardiac conduction defects ($p < 0.001$), and aortic outflow tract murmurs ($p < 0.005$) than did control patients. Patients with MAC and without aortic root calcification had a higher incidence ($p < 0.001$) of conduction defects than did patients with aortic root calcification without MAC. Control patients with and without aortic root calcification had a similar incidence of conduction defects. A higher incidence of atrioventricular block ($p < 0.025$) and bundle branch block or left anterior hemiblock or intraventricular conduction defect ($p < 0.05$) was present in anterior MAC than in posterior MAC. In conclusion, patients with MAC have a higher incidence of cardiomegaly, cardiac conduction defects, and aortic outflow tract murmurs than a control group.

Many investigators have reported the pathologic and clinical features of patients with mitral anular calcification (MAC).[1–12] In particular, studies have stressed the older age of these patients and the high frequency of cardiac failure, heart murmurs, and conduction defects. Mention has been made of the marked distortion of the mitral anulus and mitral valve secondary to dense deposits of calcium in the anulus.[2,3] In autopsy series, the calcification is reported to extend several centimeters into the left atrial or left ventricular myocardium. Involvement of the conduction system and a high frequency of concomitant aortic root calcification have been noted.

The diagnosis of MAC has been simplified recently by echocardiography. Before echocardiography, chest roentgenography or cardiac fluoroscopy was used to establish an antemortem diagnosis of MAC. However, chest roentgenography is relatively insensitive in diagnosing MAC, and cardiac fluoroscopy is performed infrequently. Hence, data on MAC compiled before echocardiography were primarily obtained from autopsy series.

Several investigators have described the echocardiographic and clinical findings in patients with MAC.[5,7,8,10] However, their patients would be expected to have an increased frequency of heart murmurs, cardiomegaly, and conduction defects on the basis of older age, concomitant disease, aortic root calcification, or other cardiac disorders. Therefore, we compared the clinical and echocardiographic features of 104 patients with MAC with those of 121 age- and sex-matched control subjects.

Methods

We retrospectively reviewed for MAC all M-mode echocardiograms taken at the Creighton University Cardiac Center since 1974. Group 1 consisted of 104 consecutive patients with MAC detected by M-mode echocardiography. Group 2 con-

* $p < 0.001$.
† $p < 0.005$.

sisted of 121 patients without MAC determined by M-mode echocardiography selected as a control group. The control group was matched for age and sex with Group 1 patients without knowledge of any other clinical and laboratory information.

Of 104 patients with MAC, 53 (51%) were women and 51 (49%) men. Of 121 control patients, 62 (51%) were women and 59 (49%) men. The mean age of the patients with MAC was 70.5 ± 8.9 years and that of the control group 69.4 ± 8.3 years.

All M-mode echocardiograms were taken with a commercially available ultrasonograph using a 1.27 cm, 2.25 MHz, medium-focus transducer and a strip chart recorder. Posterior MAC was identified when a band of dense echoes was recorded anterior to the left ventricular posterior wall and moving parallel with it (Fig. 1). These echoes terminated at the atrioventricular junction and merged with the left ventricular posterior wall on echocardiographic sweep from the aortic root to the left ventricular apex. Anterior MAC was identified when a continuous band of dense echoes was noted at the level of the anterior mitral valve leaflet in both systole and diastole (Fig. 1). This echo-dense band was contiguous with the posterior wall of the aortic root. Aortic root calcification was identified when dense echoes were noted within the aortic root in both systole and diastole (Fig. 1). This finding was not necessarily associated with calcification or decreased excursion of aortic leaflets.

The heart murmurs were classified on the basis of auscultatory and phonocardiographic findings. A systolic ejection murmur recorded along the left sternal border or second right intercostal space was classified as an aortic outflow tract murmur. An apical holosystolic or late systolic murmur was classified as a mitral regurgitation murmur. A diastolic decrescendo murmur beginning with A_2 located along the right or left sternal border or at the apex was classified as an aortic regurgitation murmur. A mid-diastolic murmur at the apex with or without presystolic accentuation was categorized as a mitral stenosis murmur.

Chest roentgenograms in each patient were assessed for cardiomegaly.[13] Chamber enlargement by M-mode echocardiography in each patient was determined using previously described criteria.[14] Surface electrocardiograms in each patient were evaluated for conduction defects. Patients who had sinoatrial block, sinus arrest, or the tachycardia-bradycardia syndrome were classified as having sinoatrial disease. All measurements of heart size by chest roentgenography, echocardiographic measurements, and electrocardiographic interpretations were performed by us independently of knowledge of other clinical and laboratory information. The echocardiograms were read without knowledge of the electrocardiographic information and vice versa.

Statistical analyses were performed by our biostatistician using the chi-square test and Student's t test when appropriate.

TABLE III Incidence of Conduction Defects in the Control Group

	n	Conduction Defect	
		n	%
Total group	121	44	36
Patients with aortic root calcification	20	8	40

Results

Table I contains clinical data on the 104 patients with MAC and the 121 control patients and any statistical differences. Table II shows the incidence of conduction defects in the subgroups of patients with MAC and any statistical differences. Sixty-eight patients with MAC had concomitant aortic root calcification, and 36 patients with MAC did not have aortic root calcification. Table III indicates the incidence of conduction defects in the 121 control patients and in the 20 control patients with aortic root calcification. No significant difference in the incidence of conduction defects occurred in the control patients with or without aortic root calcification.

Of 104 patients with MAC, 79 (76%) had conduction defects, compared with 44 (36%) of 121 control patients (chi-square = 35.39, $p < 0.001$). Twenty-six (72%) of 36 patients with MAC and without aortic root calcification had conduction defects, compared with 44 (36%) of 121 control patients with aortic root calcification (chi-square = 14.44, $p < 0.001$).

Forty (75%) of 53 women and 39 (76%) of 51 men with MAC had conduction defects. Seventeen (27%) of 62 women in the control group and 27 (46%) of 59 men in the control group had conduction defects (chi-square = 4.40, $p < 0.05$). A greater incidence of conduction defects occurred in women with MAC than in women in the control group (chi-square = 26.39, $p < 0.001$). A greater incidence of conduction defects occurred in men with MAC than in men in the control group (chi-square = 10.75, $p < 0.005$).

Discussion

On the basis of previous reports, M-mode echocardiography appears more sensitive than cardiac fluoroscopy in detecting MAC.[5,7,8,10] Anatomic studies have documented the correlation of location of calcification with specific conduction defects. However, to our knowledge, no previous echocardiographic study has evaluated the association between the different locations of MAC and the incidence and types of various conduction defects.

Previous studies have emphasized the greater incidence of MAC in women than in men. However, the incidence of MAC was similar in men and women in our study. This finding agrees with a previous report by Roberts and Perloff.[3]

Precordial murmurs are frequently described in patients with MAC. The greater incidence of heart murmur in our patients with MAC than in the control group was due to a higher incidence of aortic outflow tract murmurs.

Our study confirms previous reports that MAC is associated with conduction defects.[2,8–10,12] In our study this association was independent of age, sex, or conditions such as coronary artery disease, rheumatic heart disease, hypertension, or diabetes mellitus. A greater incidence of atrioventricular block and bundle branch block or left anterior hemiblock or intraventricular conduction defect was present in anterior MAC than in posterior MAC.

Acknowledgment: We thank Kay Ryschon, MS, for statistical analysis of the data and Ann Hensleigh for typing the manuscript.

Prosthetic Mitral Valve Motion During Cardiac Dysrhythmias As Determined by Echocardiography

IOANNIS P. PANIDIS, MD, JOEL MORGANROTH, MD, DANIEL DAVID, MD, CHIN C. CHEN, MD, and MORRIS N. KOTLER, MD

To assess the changes and physiologic mechanisms of prosthetic valve motion during cardiac dysrhythmias as well as the role of atrial systole in the closure of the mitral valve, M-mode echocardiography was performed in 36 patients with normally functioning prosthetic mitral valves (Björk-Shiley, Starr-Edwards, and Beall valve). Premature closure of the prosthetic mitral valve in diastole with a "sharp" closing motion was seen during first-degree atrioventricular block, atrial fibrillation with ventricular rates <60 beats/min, and atrial flutter. A "rounded" premature valve closure due to atrial systole was seen during atrial tachycardia and complete heart block. Atrial systole initiates a closing motion of the prosthetic mitral valve at end-diastole, and ventricular systole completes this closure during normal sinus rhythm. When first-degree atrioventricular block is present, atrial systole alone completes this closure before ventricular contraction. Atrial contraction alone also can effectively close the prosthetic mitral valve during atrial flutter and atrial tachycardia. Other factors (such as left ventricular diastolic volume) may play a role in the effective closure of the prosthetic mitral valve during atrial fibrillation with slow ventricular rates and complete heart block. These findings must be considered in the echocardiographic evaluation of suspected malfunctioning prosthetic mitral valves. A baseline postoperative echocardiogram after prosthesis insertion is important for future evaluation when clinically indicated.

The complex mechanics of mitral valve motion have been the subject of numerous studies[1–15] dating back to Baumgarten[1] in 1843. More recent echocardiographic studies of normal mitral valve motion have further enhanced our understanding of its function during normal and abnormal rhythms.[16–23] M-mode echocardiographic patterns of many of the various types of mitral prosthetic valves have also been described,[24–33] but the specific motion patterns during various cardiac dysrhythmias have not been elucidated.

This study details the effect of various rhythm and conduction disturbances on the M-mode echocardiographic motion pattern of the most commonly used, *normally functioning* prosthetic mitral valves, with special emphasis on the physiologic mechanisms of mitral valve closure.

Methods

The study involved 36 patients (27 women and 9 men) with a mean age of 57 ± 8 (standard deviation [SD]) years. These persons had undergone isolated mitral valve replacement for a variety of disease entities (Table I). A Björk-Shiley tilting disc valve prosthesis was inserted in 26 patients, a Starr-Edwards caged-ball prosthesis in 6 and a Beall parallel (nontilting) moving disc valve in 4. No patient had signs or symptoms of a malfunctioning prosthetic mitral valve.

M-mode echocardiography was performed utilizing either a focused phased-array ultrasound system (Varian V-3000) in which an M-mode echocardiogram can be selected and recorded from a single arc of the 2-dimensional echo display, or utilizing an Advanced Technology Laboratories (Mark III) system with a 2.25 MHz transducer. Echocardiograms and electrocardiograms were simultaneously recorded on strip chart format using a paper speed of 50 mm/s.

The echocardiogram of the mitral valve prosthesis was taken with the transducer initially placed at the left parasternal border in the third or fourth intercostal space oriented perpendicularly to the chest wall. The orientation of the echo beam was adjusted in each instance to obtain the maximal excursion of the prosthetic valve. Patients with Starr-Edwards valves were examined with the transducer placed at the cardiac apex and directed up toward the left atrium, since the ball moves in a superior-inferior plane.

AF = atrial fibrillation; B-S = Björk-Shiley prosthetic valve; CMA = calcified mitral anulus; MVP = mitral valve prolapse; NSR = normal sinus rhythm; RHD = rheumatic heart disease; SBE = subacute bacterial endocarditis; SD = standard deviation; S-E = Starr-Edwards prosthetic valve.

Each patient had 1 to 4 separate M-mode echocardiograms from 1 day to 15 years after mitral valve replacement. Normal sinus rhythm was present in 15 studies, atrial fibrillation in 25 studies, atrial flutter in 3 studies, and atrial tachycardia in 1 study (Table I). In addition, echocardiographic studies were performed during various modes of cardiac pacing (2 ventricular, 2 atrioventricular sequential, and 2 atrial pacing). In 1 patient with mitral and aortic valve replacement and underlying complete heart block, M-mode echocardiograms were obtained with various heart rates using temporary ventricular pacing.

Measurements: In all patients, the heart rate was expressed as the R-R interval in milliseconds (ms), and the longest and shortest R-R interval of each echocardiographic study was noted in patients with atrial fibrillation. The Q-C interval in milliseconds was measured from the onset of the QRS complex to the point of complete closure of the prosthetic mitral valve at end-diastole. The P-R interval was expressed in milliseconds. Differences in groups were assessed by the 2-tailed Student's t test. The values reported represent means ± standard deviation.

Results

M-mode echocardiographic patterns of various types of normally functioning mitral prosthetic valves: A characteristic M-mode echocardiographic motion pattern was observed for each type of mitral prosthetic valve. The Björk-Shiley tilting disc valve (26 patients) demonstrated an early diastolic rapid upward opening motion of the disc which maintained an open position throughout diastole and was followed by a brisk downward closing motion at the end of diastole. The edges of the disc are peaked and can be clearly seen on the M-mode echocardiographic recordings (Fig. 1). The Starr-Edwards ball valve (6 patients) showed round edges and a more gradual opening and closing motion; its diastolic motion resembles the echocardiographic pattern of mitral stenosis (Fig. 2). The Beall disc valve (4 patients) demonstrated a gradual opening and closing motion with sharp, clearly defined edges of the disc and a smaller amplitude of excursion.

Echocardiographic features of the mitral prosthetic valves during dysrhythmia: No significant difference in the echocardiographic motion pattern and closure between the various types of prosthetic valves were seen during dysrhythmia. Thus, the following findings during different arrhythmias were similar for each individual type of valve prosthesis.

Normal sinus rhythm: Fifteen M-mode echocardiograms of prosthetic mitral valve were obtained during normal sinus rhythm (NSR) in which the mean R-R interval was 791 ± 99 ms.

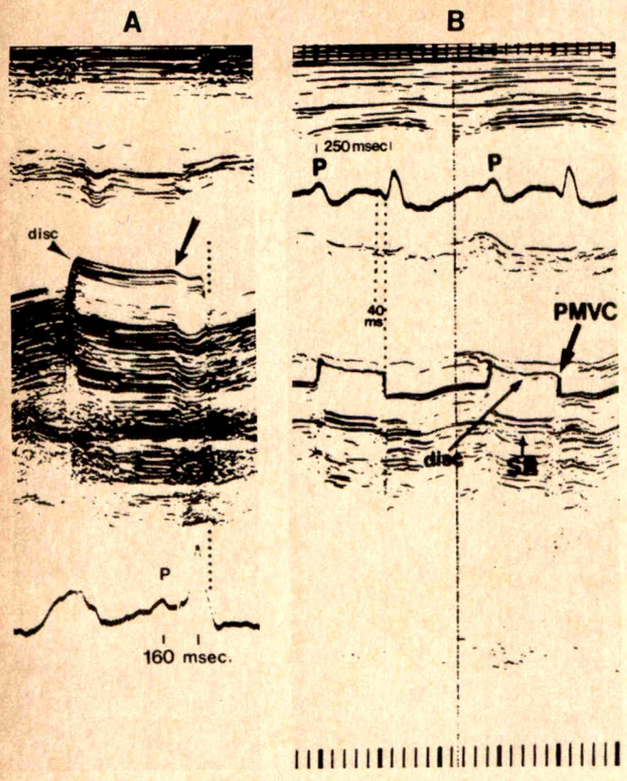

FIGURE 1. Björk-Shiley tilting disc valve in mitral position during sinus rhythm with normal (**A**) and prolonged P-R interval (**B**) is shown. A brisk opening and closing motion of the disc with sharp edges are seen. **A,** a late diastolic "hump" (**large arrow**) corresponding with the atrial contraction (P wave) is noted during sinus rhythm with P-R interval of 160 ms, and the Q-C interval is 70 ms (**dotted line**). **B,** during a prolonged P-R interval of 250 ms, premature mitral valve closure (PMVC) is noted with a Q-C interval of 40 ms (**between dotted lines**). SR = sewing ring.

A late diastolic anterior motion ("hump") on the prosthetic mitral valve echocardiogram was observed in NSR induced by atrial contraction (Fig. 1A).

In 10 of the 15 echocardiographic studies during normal sinus rhythm (mean R-R interval 792 ± 76 ms) the P-R interval was normal (mean 167 ± 18 ms, range 140 to 195). In this group, the Q-C interval was 60 to 80 ms (mean 68 ± 7) (Fig. 1A and 3).

In 5 other studies with a mean R-R interval of 788 ± 146 ms, the P-R interval was prolonged (mean 284 ± 82 ms, range 200 to 390). In this group, the prosthetic valve closed earlier; the Q-C interval was always ≤60 ms (range 20 to 60, mean 40 ± 18) ($p < 0.001$) (Fig. 1B and 3). In general, the longer the P-R interval, the earlier the prosthetic mitral valve closed during end-diastole. No patient had evidence of acute severe aortic regurgitation.

Atrial fibrillation: Twenty-five M-mode echocardiographic studies of various prosthetic mitral valves were obtained during atrial fibrillation. Due to the lack of atrial systole, no diastolic "humps" on the prosthetic mitral valve could be observed. After the initial opening motion, the prosthetic mitral valve maintained an open position throughout diastole (Fig. 2). In 1 patient, however, with R-R interval of 850 ms, partial closure in mid-diastole and reopening was seen.

The shortest and longest R-R intervals in each study and the corresponding Q-C interval in milliseconds were measured. In all types of prosthetic valves, during longer R-R intervals (slow ventricular rates), the valve closed earlier than in cases in which the R-R intervals were shorter (faster ventricular rates) (Fig. 4). In 13 studies with R-R intervals >1,000 ms, mean 1,190 ± 167, the Q-C interval was always ≤70 ms, mean 63 ± 8, and decreased to 45 ms with the longest R-R interval of 1,520 ms (Fig. 2A and 4).

In 37 studies with R-R intervals <1,000 ms (mean 665 ± 169), the Q-C interval was always ≥70 ms (mean 80 ± 11) ($p < 0.001$) and increased to 105 ms with the shortest R-R interval of 400 ms (Fig. 2B and 4).

Atrial flutter: Three patients with a Björk-Shiley mitral prosthesis were studied during atrial flutter. In these 3 studies (1 with 2:1 atrioventricular block and 2 with 4:1 atrioventricular block) the R-R interval was 500 to 750 ms and the Q-C interval 60 to 70 ms. The prosthetic mitral valve remained open throughout diastole in 2 of the 3 studies. In 1 study with an atrial rate of 240 beats/min during a sudden change in the atrioventricular conduction ratio from 2:1 to 3:1, a mid-diastolic closing of the prosthetic valve was followed by reopening of the valve in late diastole by the following atrial contraction (F wave) (Fig. 5).

Atrial tachycardia: One patient with an atrial rate of 220 beats/min had variable atrioventricular block. The Björk-Shiley prosthetic valve demonstrated partial or complete early diastolic closure. Subsequent late diastolic P waves were followed by reopening of the prosthetic valve, which closed at the onset or end of QRS complex, but always 140 ms from the peak of the preceding P wave (Fig. 6). Hence, the onset of systole did not initiate mitral valve closure. A rounded opening and closing motion of the prosthetic valve was observed whenever this motion was induced by atrial systole (Fig. 6).

Pacing studies: Six echocardiographic studies of the Björk-Shiley prosthetic mitral valve were obtained in various modes of cardiac pacing and the differences of the echocardiographic motion pattern and closure of the prosthetic valve in these modes of pacing were examined.

Ventricular pacing: In 1 of the 2 studies with ventricular pacing, the underlying atrial rhythm was atrial fibrillation. The cycle length was 1,050 ms and the diastolic mitral valve opening was of constant duration at a fixed rate of ventricular pacing. The prosthetic valve remained open throughout diastole and closed 80 ms after the onset of the QRS complex.

In 1 patient with underlying complete heart block, the motion of the Björk-Shiley valve was recorded during various rates of ventricular pacing (Fig. 7, top and center). When the ventricular pacing was turned off, the motion of the Björk-Shiley mitral valve was recorded during complete heart block with junctional rhythm and similar phenomena were observed as shown and described in Figure 7 (bottom).

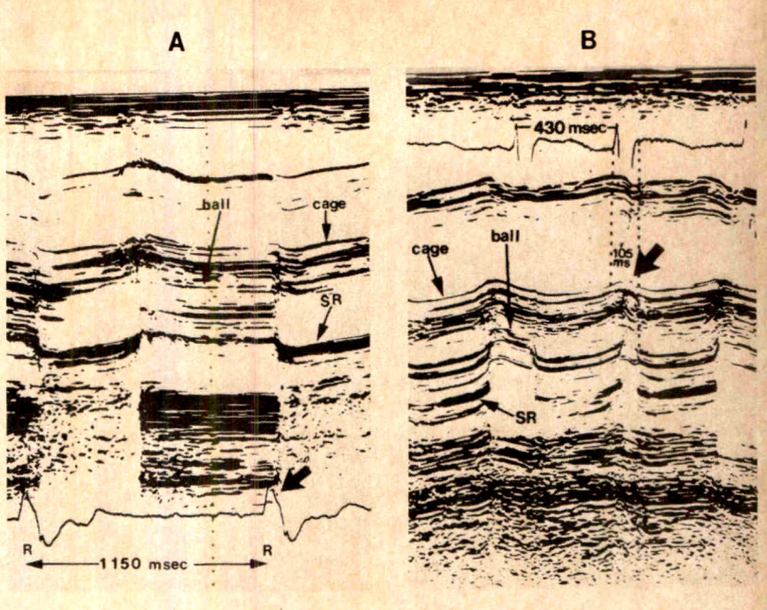

FIGURE 2. Starr-Edwards ball-cage valve in mitral position during atrial fibrillation with slow (**A**) and rapid ventricular response (**B**) is shown. The round edges of the valve are noted. **A,** the Q-C interval during the long R-R interval (1,150 ms) is 65 ms (**large arrow**). **B,** the Q-C interval is 105 ms (**between dotted lines**) during the short R-R interval (430 ms) (**large arrow**). SR = sewing ring.

A diastolic notch on the prosthetic mitral valve corresponding to the atrial contraction (P wave) was seen in these studies (Fig. 7). A rounded closing motion of the prosthetic mitral valve was observed during the atrial systole-induced closure of the valve, while the closing motion of the valve was sharp when the ventricular systole completed the prosthetic valve closure (Fig. 7).

Atrial pacing: The 2 patients with Björk-Shiley valve and atrial pacing had a prolonged atrioventricular conduction time (360 and 380 ms, respectively); as expected, the prosthetic valve remained open throughout diastole and closed early at end-diastole, 40 ms after the onset of QRS complex.

Atrioventricular pacing: One of the 2 patients with Björk-Shiley valve and atrioventricular sequential pacing had a prolonged atrioventricular interval of 270 ms; the prosthetic valve sometimes demonstrated premature closure at end-diastole before the onset of QRS complex, or partial closure in mid-diastole and reopening at end-diastole.

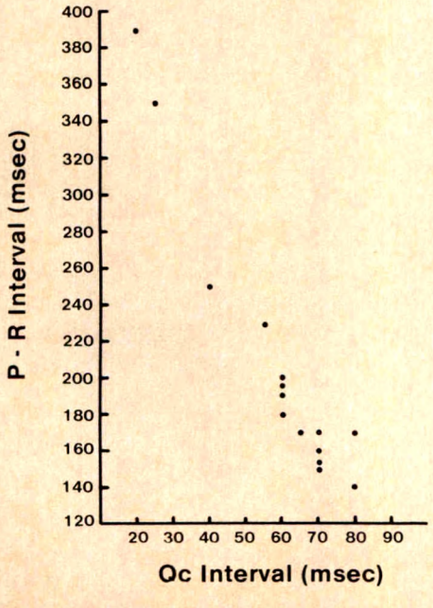

FIGURE 3. Relation between the P-R interval (**ordinate**) and onset of QRS to closing point of the prosthetic valve interval (Q-C interval) (**abscissa**) is shown during sinus rhythm. Note the earlier mitral valve closure with prolongation of the P-R interval.

Discussion

This and previous echocardiographic studies have described the motion of the most commonly used, normally functioning prosthetic valves in the mitral position.[24–33] These echocardiographic patterns can identify which type of valve is imaged and determine possible valve malfunction. Signs of malfunction described include clot formation around the valve,[34–36] rounded and slowed pattern of opening and closure,[37–40] or intermittent, delayed, or incomplete opening of the valve[40–43] due to clot formation, and early diastolic "hump" due to perivalvular leak.[37,44,45]

Cardiac arrhythmias can also influence the normal echocardiographic pattern of the prosthetic valves and result in altered motion patterns, which may mimic some of the echocardiographic signs of malfunctioning prosthetic valve. In the present study we describe the specific M-mode echocardiographic motion patterns and closure characteristics of mitral prosthetic valves during various cardiac dysrhythmias, emphasizing the physiologic mechanisms of their closure.

There was no difference between the various types of artificial prosthetic valves in the motion and closure characteristics induced by dysrhythmias; thus, our observed findings apply to each type of prosthesis.

Effect of the P-R interval on mitral closure pattern: The normal interval from the onset of the QRS

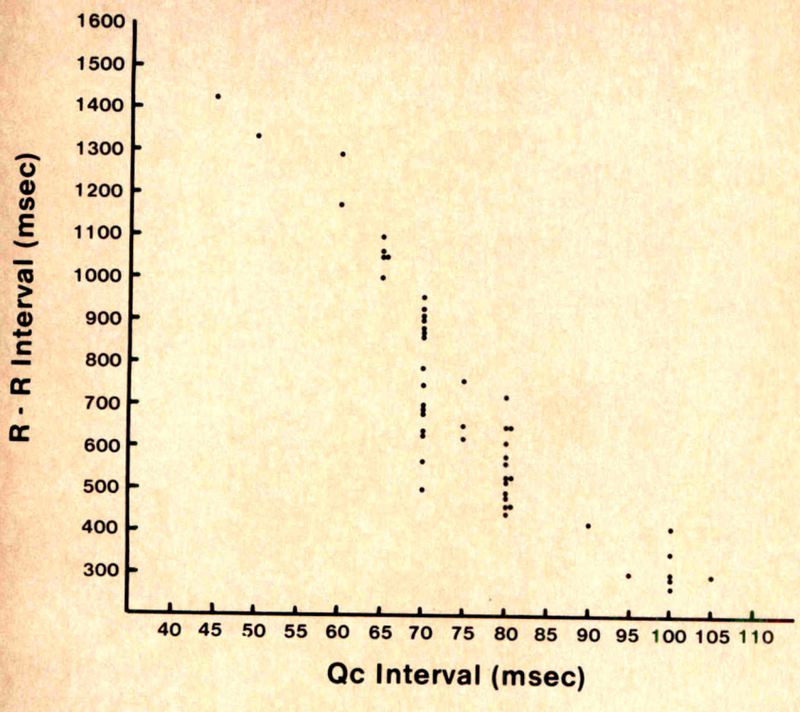

FIGURE 4. Relation between the R-R interval (**ordinate**) and onset of QRS to closing point of the prosthetic valve interval (Q-C interval) (**abscissa**) is shown during atrial fibrillation. Note the earlier mitral valve closure with long R-R intervals (slower ventricular rates).

complex to the onset of left ventricular systole is 52 ms.[46] Pohost et al[20] described a good correlation between the echocardiographically defined mitral valve closure and the hemodynamic indicators of its closure. The onset of left ventricular systole occurred 25 ± 10 ms before the termination of the final rapid posterior motion of the mitral valve by echocardiography. The normal interval from the onset of the QRS complex to the echocardiographic closure of the mitral valve is 77 ± 10 ms.[20,46] Other studies[22,47] reported an average QRS-to-closure click interval of 63 to 73 ms during sinus rhythm with normal P-R interval in patients with normally functioning Starr-Edwards mitral valve prostheses. We found a similar mean Q-C interval of 68 ± 7 ms (SD) by M-mode echocardiography in patients with various prosthetic mitral valves, most commonly Bjork-Shiley type, who were in sinus rhythm with a normal P-R interval (Fig. 3).

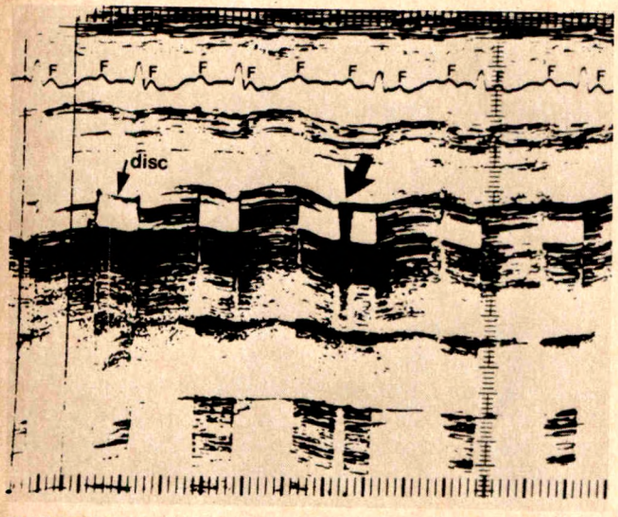

FIGURE 5. Björk-Shiley prosthetic valve in mitral position during atrial flutter with 2:1 atrioventricular block is shown. During a sudden change in the atrioventricular conduction ratio from 2:1 to 3:1 (**large arrow**), the prosthetic valve closes in mid-diastole and is reopened in late diastole by the following atrial contraction (F = flutter wave). Note the abrupt opening and closing motion of the valve. The Q-C interval is 60 ms.

It appears, therefore, that during sinus rhythm with normal P-R interval, the hemodynamics of closure of a prosthetic mitral valve are similar to those of the normal mitral valve, influenced directly by the left ventricular-left atrial pressure gradient and mitral valve flow.[4–6,8,9] Atrial systole results in an augmentation of the left ventricular pressure and initiates the closure of the prosthetic mitral valve. Valve closure is then completed by the pressure developed by left ventricular contraction.[10,14,15,22]

A late diastolic "hump" on the prosthetic mitral valve echocardiogram was frequently observed, corresponding to the P wave on the electrocardiogram (Fig. 1A), representing the effect of atrial contraction. This late diastolic "hump" should be distinguished from the early diastolic "hump" on a prosthetic valve, which may indicate a perivalvular leak[37,44,45] or clot formation,[39] and from an early diastolic notch on a Beall[48] or Starr-Edwards valve indicating valve variance.

Premature mitral valve closure in first-degree atrioventricular block has been demonstrated by several experimental[14,16,19] and clinical studies of the normal[49] or prosthetic mitral valve.[22,50–52] Zaky et al[16] showed complete or incomplete presystolic mitral valve closure in patients with a P-R interval ≥180 ms. We also observed that in the presence of sinus rhythm with a P-R interval ≥200 ms, the prosthetic mitral valve closed

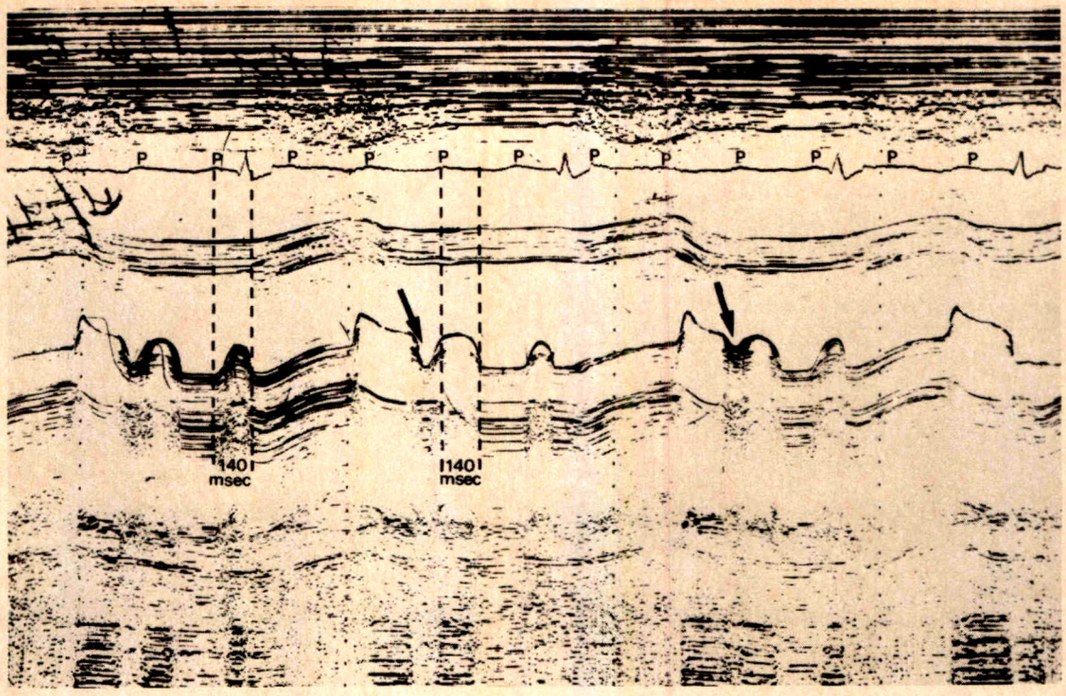

FIGURE 6. Björk-Shiley prosthetic valve in mitral position is shown during atrial tachycardia with variable atrioventricular block demonstrating partial or complete closure in early diastole (**arrows**) and reopening of the valve by subsequent late diastolic P waves. The valve closes consistently 140 ms from the peak of the preceding P wave. Notice the rounded opening and closing motion induced by the atrial systole.

earlier at end-diastole with a mean Q-C interval of 40 ± 18 ms ($p < 0.001$) (Fig. 1B); the Q-C interval shortened as the P-R interval lengthened (Fig. 3).

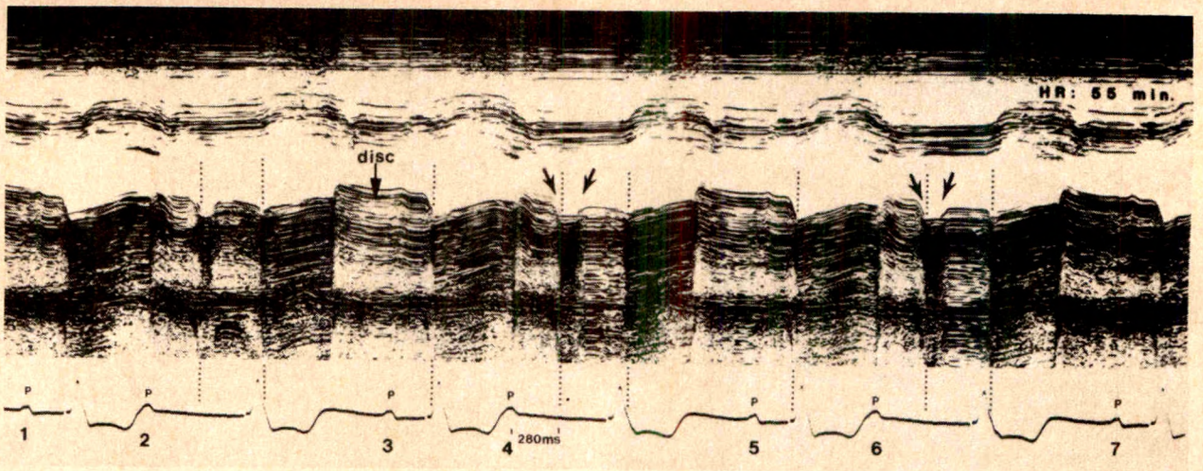
The prolonged atrioventricular conduction permits the atrial contraction to influence the closure of the prosthetic valve before the ventricle contracts. Thus, a mid-diastolic reversal of the mitral flow and a ventriculoatrial pressure gradient induced by the atrial systole results in premature, partial, or complete valve closure before the onset of ventricular contraction[5,8,16,19] and possible presystolic mitral regurgitation.[14]

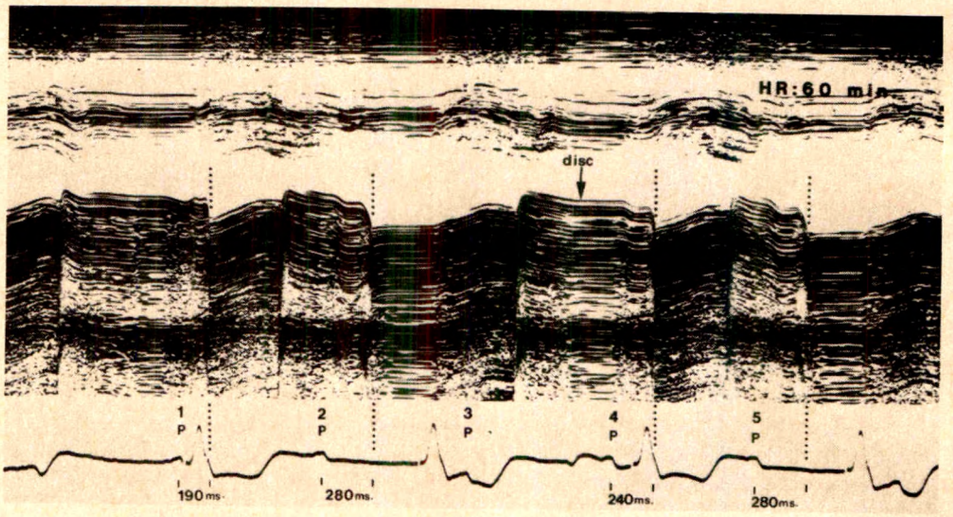
The hemodynamic consequences of this premature valve closure in first-degree atrioventricular block are not well known. Williams and Wood[53] observed that there is an optimal P-R interval, varying with heart rate, beyond which stroke volume and systolic pressure tend to decrease. Moreover, it is clinically important to recognize the occurrence of the premature prosthetic valve closure in first-degree atrioventricular block, since this phenomenon has also been observed in patients with prosthetic mitral valve and acute severe aortic regurgitation.[54,55]

Atrial fibrillation: Several experimental studies of the hemodynamic effects of atrial fibrillation suggested that mitral regurgitation may occur as a result of atrial fibrillation with relatively slow ventricular rates.[23,56–58] The motion of the normal and prosthetic mitral valve during atrial fibrillation has also been studied by M-mode echocardiography.[22,59–61] In patients with Starr-Edwards valves and atrial fibrillation, Hamby et al[22] found an average QRS-to-closure click interval of 86 ± 5 ms, determined by phonocardiography. An inverse relation between the length of the preceding R-R cycle and the Q-C interval of the prosthetic mitral valve has been demonstrated in atrial fibrillation.[49,62–64] We also observed that with R-R intervals >1,000 ms (ventricular rates <60 beats/min), the Q-C interval was always ≤70 ms, mean 63 ± 8 (Fig. 2A and 4). In contrast with R-R intervals <1,000 ms (ventricular rates >60 beats/min), the Q-C interval was always ≥70 ms, mean 80 ± 11 ms ($p < 0.001$) (Fig. 2B and 4).

These findings demonstrate that in atrial fibrillation, in which the effect of atrial systole is lost, the closure of the prosthetic mitral valve is due to the ventricular contraction when the ventricular response of atrial fibrillation is >60 beats/min. On the other hand, with ventricular rates <60 beats/min, the closure of the prosthetic mitral valve is not accomplished by the ventricular contraction. The mechanism of this early closure of the prosthetic mitral valve during atrial fibrillation with prolonged filling periods may be associated with an increment in left ventricular pressure, resulting in a ventriculoatrial gradient across the mitral valve or the development of a critical left ventricular volume—the "locking" volume—adequate to close the valve without ventricular contraction.[23] Another explanation may be due to the reflection of incoming jets of blood off the apex of the left ventricle during early diastole resulting in ring vortex formation and premature closure of the mitral valve, and the effect of gravity reported in all valve prostheses.[65]

Atrial flutter: The echocardiographic motion pattern of the normal mitral valve in atrial flutter has been described,[59,60,66–68] but only in 2 patients with a pros-





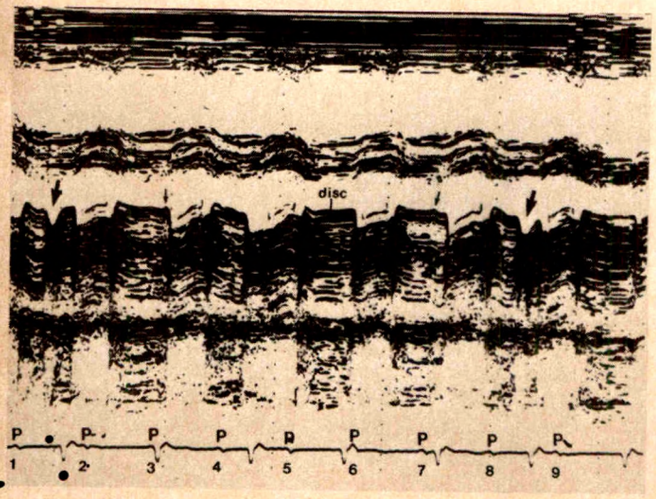


FIGURE 7. Björk-Shiley prosthetic valve in mitral position is shown during complete heart block and various rates of ventricular pacing. **Top,** at a pacing rate of 55 beats/min, the prosthetic valve closes in mid-diastole with a rounded motion (**arrows**) 280 ms after the peak of a P wave occurring early in diastole with a P-R interval of 650 ms (second, fourth, and sixth P waves) and reopens in late diastole to be closed 80 ms after the onset of QRS complex. When the P wave occurs late in diastole with a P-R interval of 290 ms (first, third, fifth, and seventh P waves), the prosthetic valve remains open throughout diastole and closes at the onset of QRS complex, 280 ms after the peak of the P wave. **Center,** at a pacing rate of 60 beats/min, the prosthetic valve closes in mid-diastole with a round motion, 280 ms after the peak of P waves (second and fifth P waves) occurring early in diastole (P-R interval 600 and 580 ms, respectively), but does not reopen during the rest of diastole. When the P waves occur late in diastole (first and fourth P waves) with P-R intervals 120 and 200 ms, respectively, the prosthetic valve remained open throughout diastole and was closed by ventricular systole with an abrupt motion 80 ms after the onset of QRS complex. **Bottom,** a Björk-Shiley prosthetic valve in mitral position is shown during complete heart block. With a P-R interval of 60 ms (third P wave) and 160 ms (seventh P wave), the prosthetic valve remains open throughout diastole and closes 70 ms after the onset of QRS complex. A diastolic notch is seen on the prosthetic valve (**small arrows**) corresponding to atrial contraction. With further increase in the P-R interval to 300 ms (fourth P wave), the valve closes prematurely in late diastole before the onset of QRS complex. When the P wave occurs earlier in diastole (first and eighth P waves) with P-R intervals 440 and 400 ms, respectively, the valve closes in mid-diastole and reopens (**large arrows**) to be closed 70 ms after the onset of QRS complex. With even longer P-R intervals (second, fifth, and ninth P waves) of 660, 520, and 640 ms, respectively, the valve remains open throughout diastole and closes 70 ms after the onset of QRS complex.

thetic mitral valve (Starr-Edwards ball valve).[60,67] In 1 patient with Björk-Shiley mitral valves, mid-diastolic closure of the prosthetic mitral valve was observed after a flutter wave with reopening in late-diastole during a sudden change of the atrioventricular conduction ratio from 2:1 to 3:1 (Fig. 5). This early diastolic closure of the mitral valve during atrial flutter with >2:1 atrioventricular block also has been observed by others in normal subjects[59,66] and in patients with prosthetic mitral valve.[60] Flutter waves, therefore, can generate an effective atrial contraction which opens and then closes the prosthetic mitral valve by raising the left ventricular diastolic pressure and reversing the atrioventricular pressure gradient.[60] Due to the shortened diastolic time, the atrial-induced early diastolic closure of the mitral valve is not seen during atrial flutter with 2:1 atrioventricular conduction (Fig. 5).

Atrial tachycardia: There have been only a few echocardiographic case reports of the motion of the normal mitral valve during supraventricular tachycardias.[68–70] We observed a unique echocardiographic motion pattern of the Björk-Shiley prosthetic mitral valve in atrial tachycardia with varying atrioventricular block (Fig. 6). The prosthetic mitral valve closed partially or completely in early diastole and was subsequently opened and closed with a rounded motion by the following P waves independently from the ventricular contraction (Fig. 6), in contrast to atrial flutter where the opening and closing motion of the prosthetic valve was sharp (Fig. 5).

This demonstrates that atrial contraction induced by the atrial tachycardia P waves can also effectively open and close the prosthetic mitral valve without the contribution of the ventricular systole.

Paced rhythm: Two patients with Björk-Shiley mitral valve and atrial pacing with prolonged atrioventricular conduction demonstrated, as expected, premature closure of the prosthetic valve at end-diastole, 40 ms after the onset of QRS complex. One patient, however, with atrioventricular sequential pacing and prolonged atrioventricular interval demonstrated incomplete closure and reopening or premature closure at end-diastole, but always before the onset of the QRS complex. This difference in closure characteristics in these 2 modes of pacing is not clearly understood.

On the other hand, in a patient with ventricular pacing and underlying atrial fibrillation, the prosthetic mitral valve remained open throughout diastole and was closed by ventricular systole. In another patient with Björk-Shiley valve and underlying complete heart block, the motion of the prosthetic mitral valve was recorded at various ventricular pacing rates and off pacing (Fig. 7). Atrial systole coincident with early diastolic P waves induces a rounded mid-diastolic closing motion of the prosthetic valve which may reopen in late diastole and finally be closed at end-diastole by the ventricular systole with a sharp closing motion (Fig. 7, top and center). This patient had symptoms of dizziness and hypotension (so-called "pacemaker syndrome"), probably due in part to premature mitral valve closure from early occurring P waves in diastole. Similar phenomena were observed with the pacemaker turned off with complete heart block being present (Fig. 7, bottom). These findings are in agreement with other echocardiographic studies of patients with complete heart block and normal mitral valve[16,21] which demonstrated that with prolonged P-R intervals there was early closure and reopening of the mitral valve in diastole and secondary closure initiated by ventricular systole.

The hemodynamic effects of cardiac pacing have been examined in animal studies utilizing echocardiography[71] but not in humans. The importance of a physiologic atrioventricular sequencing during cardiac pacing has been shown[72] and our findings demonstrate the potential application of M-mode echocardiography in the evaluation of patients with various pacing modes and symptoms of the "pacemaker syndrome."

Although our study is retrospective, our findings provide important morphologic, physiologic, and clinical information in patients with prosthetic mitral valves during various cardiac dysrhythmias and should be considered in the echocardiographic evaluation of suspected malfunctioning prosthetic mitral valves. We recommend baseline postoperative echocardiograms in all patients with prosthetic mitral valves so that more information can be obtained from repeat studies when clinically indicated.

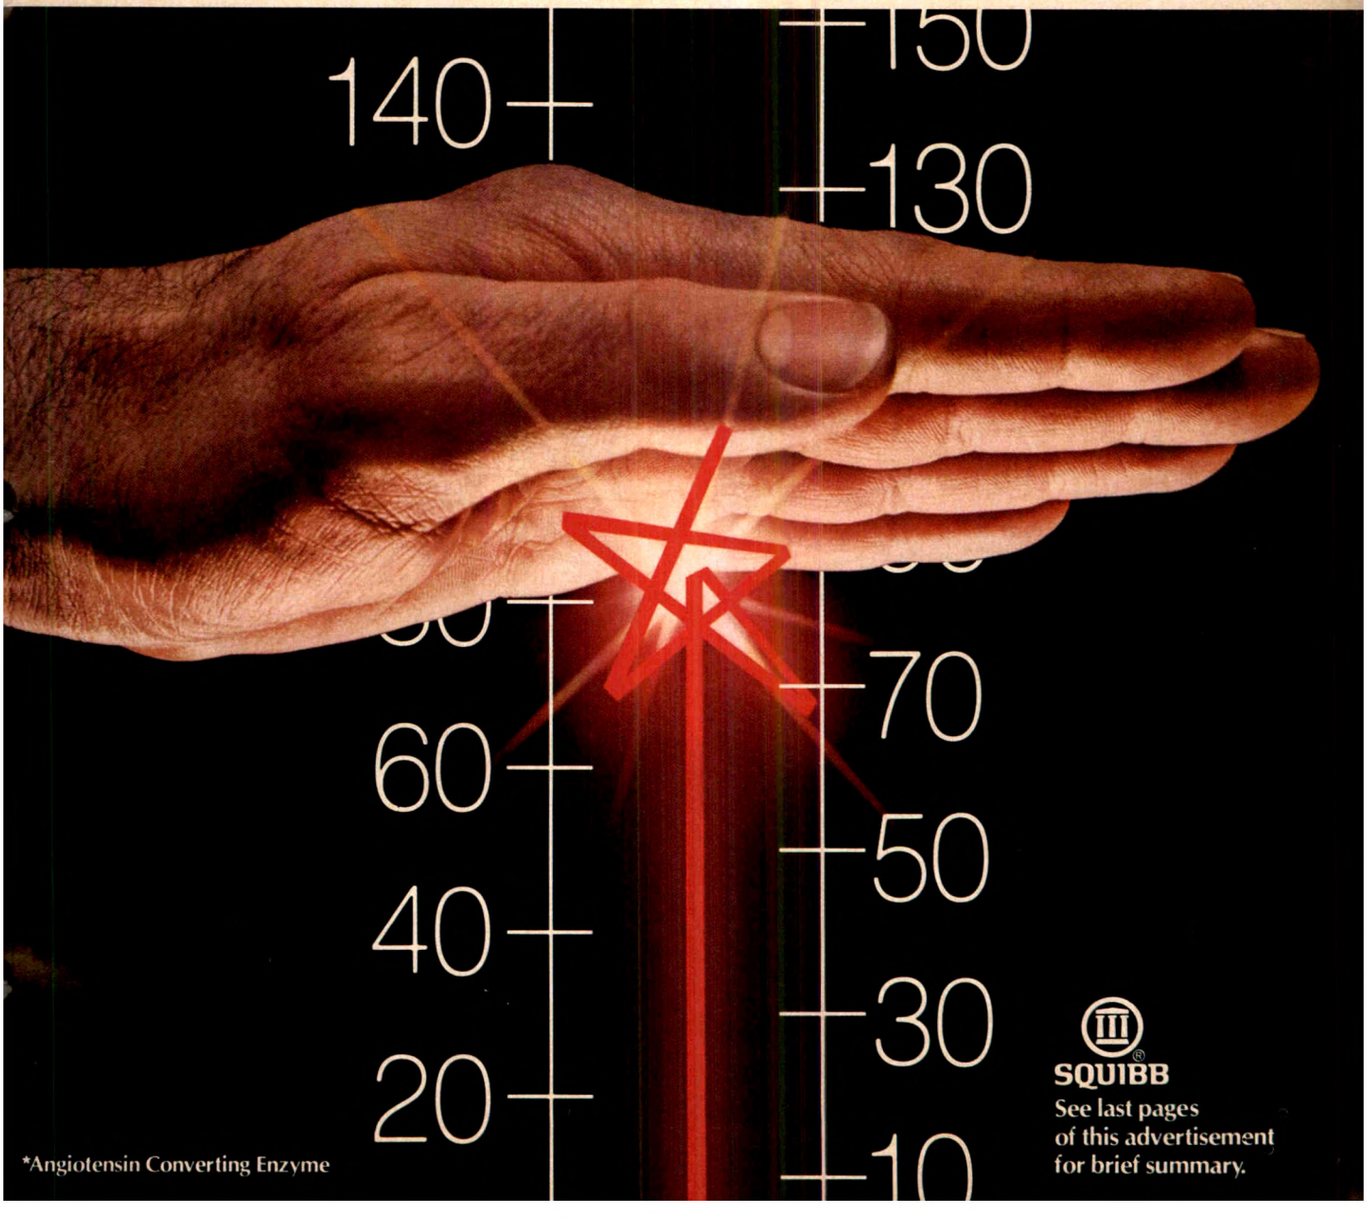
Designed to achieve your therapeutic goals in hypertension

ACE* INHIBITOR

CAPOTEN® (captopril tablets)

For hypertensive patients

- **Who experience unacceptable side effects with beta blockers, antiadrenergic agents, or vasodilators**
- **In whom standard multidrug regimens are ineffective in controlling blood pressure**
- **Who have concomitant conditions contraindicating use of other antihypertensive agents**



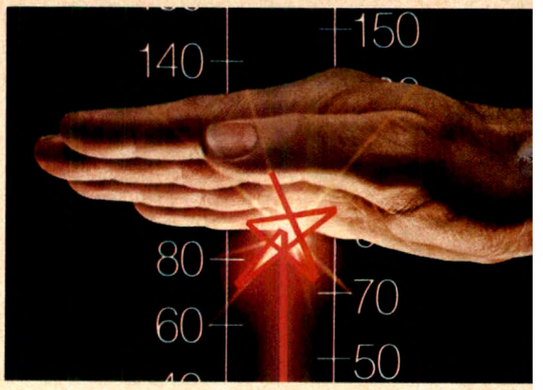
SQUIBB®

See last pages of this advertisement for brief summary.

*Angiotensin Converting Enzyme

ACE* INHIBITOR

CAPOTEN®
(captopril tablets)



CAPOTEN controls blood pressure without the following usual antihypertensive side effects†:

- No cardiac depression
- No glucose intolerance
- No bradycardia
- No mental depression
- No sleep disturbances
- No nasal congestion
- No hypokalemia
- Rare impotence/loss of libido
- Rare bronchospasm
- Rare tachycardia
- Rare fatigue

CAPOTEN is appropriate therapy when coexisting disorders complicate hypertension management

Unlike some other antihypertensive agents, CAPOTEN is appropriate for use in the presence of a wide range of cardiovascular and metabolic disorders that often coexist with hypertension.

- Bronchospastic disease
- Cardiac arrhythmias
- Congestive heart failure
- Diabetes mellitus
- Hepatic disease

CAPOTEN is effective in controlling many kinds of hypertension when conventional multidrug regimens have proven inadequate

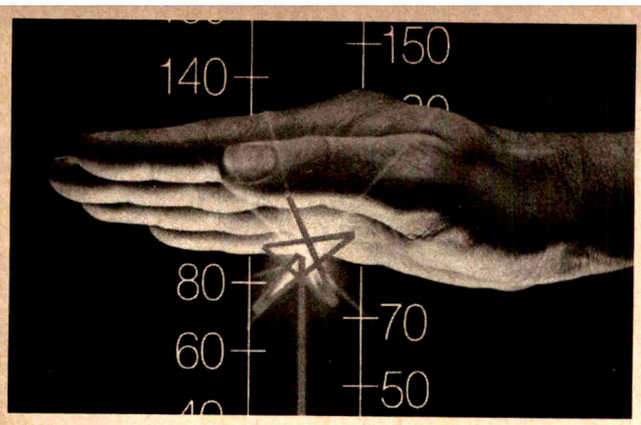
- Essential hypertension
- Hypertension resistant to standard triple therapy (STT)
- Hypertension associated with low, normal, and high plasma renin levels
- Renovascular hypertension

ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

*Angiotensin Converting Enzyme

† **Please see brief summary of prescribing information on the last pages of this advertisement for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.**



ACE* INHIBITOR

CAPOTEN®
(captopril tablets)

CAPOTEN has been associated with the development of neutropenia, agranulocytosis, or proteinuria.† These serious side effects are more likely to occur in patients with predisposing conditions, such as renal impairment or autoimmune disease, or in patients receiving therapy known to suppress the autoimmune response.

The following precautionary guidelines are recommended for all patients receiving CAPOTEN:

- **Obtain urinary protein level estimates prior to initiating therapy, at monthly intervals for the first nine months of treatment, and periodically thereafter.**
- **Obtain WBC counts at the initiation of therapy, at two-week intervals for the first three months of treatment, and periodically thereafter.**
- **Carefully review the WARNINGS and ADVERSE REACTIONS sections in the complete prescribing information, with particular attention to the patient at increased risk.**
- **The most frequently occurring adverse reactions are skin rash and taste alteration; both effects are generally mild, reversible, or self-limited.**

SQUIBB®

*Angiotensin Converting Enzyme

†Please see brief summary of prescribing information, for INDICATIONS AND USAGE, WARNINGS, and ADVERSE REACTIONS.

CAPOTEN® TABLETS
Captopril Tablets

INDICATIONS: Hypertension — Because serious adverse effects have been reported (see WARNINGS), CAPOTEN is indicated for treatment of hypertensive patients who on multidrug regimens have either failed to respond satisfactorily or developed unacceptable side effects.
Heart Failure: CAPOTEN (captopril) is indicated in patients with heart failure who have not responded adequately to or cannot be controlled by conventional diuretic and digitalis therapy. CAPOTEN is to be used with diuretics and digitalis.
WARNINGS: Proteinuria — Total urinary proteins >1 g/day were seen in 1.2% of patients on captopril; the nephrotic syndrome occurred in about ¼th of these cases. About 60% of affected patients had evidence of prior renal disease; the remainder had no known renal dysfunction. In most cases, proteinuria subsided or cleared within 6 months whether or not captopril was continued. The BUN and creatinine were seldom altered in proteinuric patients.

Membranous glomerulopathy was found in nearly all the proteinuric patients on captopril who were biopsied and may be drug related. Most cases of proteinuria occurred by the 8th month of therapy. Patients should have urinary protein estimates (dip-stick on 1st morning urine, or quantitative 24-hr urine — the latter provides greater precision when proteinuria is persistent and/or at low levels) before therapy, at approx. monthly intervals for the 1st 9 months of therapy, and periodically thereafter. For patients who develop proteinuria >1 g/day, or increasing proteinuria, the benefits and risks of continuing captopril should be evaluated.

Neutropenia/Agranulocytosis — Neutropenia (<300/mm³) associated with myeloid hypoplasia (probably drug related) occurred in about 0.3% of captopril treated patients. About half of the neutropenic patients developed systemic or oral cavity infections or other features of agranulocytosis. Most of the neutropenic patients had severe hypertension and renal function impairment; about half had systemic lupus erythematosus (SLE), or another autoimmune/collagen disorder; multiple concomitant drug therapy was common, including immunosuppressive therapy in a few cases. Daily doses of captopril in the leukopenic patients were relatively high, particularly in view of their diminished renal function. The neutropenia appeared 3 to 12 weeks after starting captopril; it developed relatively slowly, taking 10 to 30 days to have white blood count fall to its nadir; neutrophils returned to normal in about 2 weeks (other than 2 patients who died of sepsis).

Use captopril with caution in patients with impaired renal function, serious autoimmune disease (particularly SLE), or who are exposed to other drugs known to affect the white cells or immune response. In patients at particular risk (as noted above), perform white blood cell and differential counts prior to therapy, at about 2-week intervals for about the 1st 3 months of therapy, and periodically thereafter.

The risk of neutropenia in patients who are less seriously ill or who receive lower dosages appears to be smaller. In these patients white blood cell counts should be performed every 2 weeks for the 1st 3 months of therapy, and periodically thereafter. Perform differential counts when leukocytes are <4000/mm³ or the pretherapy white count is halved. All patients treated with captopril should be told to report any signs of infection (e.g., sore throat; fever); if infection is suspected, perform counts without delay. Since discontinuation of captopril and other drugs has generally led to prompt return of the white count to normal, upon confirmation of neutropenia (neutrophil count <1000/mm³) withdraw captopril and closely follow the patient's course.
Hypotension — Excessive hypotension was rarely seen in hypertensive patients but is a possibility in severely salt/volume-depleted persons such as those treated vigorously with diuretics (see PRECAUTIONS [Drug Interactions]).

In heart failure, where blood pressure was either normal or low, transient decreases in blood pressure >20% were recorded in about ½ the patients. This transient hypotension may occur after any of the first several doses and is usually well tolerated, although rarely it has been associated with arrhythmia or conduction defects. A starting dose of 6.25 or 12.5 mg tid may minimize the hypotensive effect. Patients should be followed closely for the first 2 weeks of treatment and whenever the dose of captopril and/or diuretic is increased.

BECAUSE OF THE POTENTIAL FALL IN BLOOD PRESSURE IN THESE PATIENTS, THERAPY SHOULD BE STARTED UNDER VERY CLOSE MEDICAL SUPERVISION.
PRECAUTION: General: *Impaired Renal Function,* Hypertension — Some hypertensive patients with renal disease, particularly those with severe renal artery stenosis, have developed increases in BUN and serum creatinine. It may be necessary to reduce captopril dosage and/or discontinue diuretic. For some of these patients, normalization of blood pressure and maintenance of adequate renal perfusion may not be possible. Heart Failure — About 20% of patients develop stable elevations of BUN and serum creatinine >20% above normal or baseline upon long-term treatment. Less than 5% of patients, generally with severe preexisting renal disease, required discontinuation due to progressively increasing creatinine. See DOSAGE AND ADMINISTRATION, ADVERSE REACTIONS [Altered Laboratory Findings]. *Valvular Stenosis* — A theoretical concern, for risk of decreased coronary perfusion, has been noted regarding vasodilator treatment in patients with aortic stenosis, due to decreased afterload reduction.
Surgery/Anesthesia — If hypotension occurs during major surgery or anesthesia, and is considered due to the effects of captopril, it is correctable by volume expansion.
Drug Interactions: *Hypotension: Patients on Diuretic Therapy* — Precipitous reduction of blood pressure may occasionally occur within the 1st 3 hours after administration of the initial captopril dose in patients on diuretics, especially those recently placed on diuretics and those on severe dietary salt restriction or dialysis. This possibility can be minimized by either discontinuing the diuretic or increasing the salt intake about 1 week prior to initiation of captopril therapy. Alternatively, provide medical supervision for at least 3 hours after the initial dose in hypertensive patients.
Agents Having Vasodilator Activity: In heart failure patients vasodilators should be administered with caution.
Agents Causing Renin Release — Captopril's effect will be augmented by

(Continued on next page.)

(continued from preceding page)

antihypertensive agents that cause renin release.

Agents Affecting Sympathetic Activity — The sympathetic nervous system may be especially important in supporting blood pressure in patients receiving captopril alone or with diuretics. Beta-adrenergic blocking drugs add some further antihypertensive effect to captopril, but the overall response is less than additive. Therefore, use agents affecting sympathetic activity (e.g., ganglionic blocking agents or adrenergic neuron blocking agents) with caution.

Agents Increasing Serum Potassium — Give potassium-sparing diuretics or potassium supplements only for documented hypokalemia, and then with caution, since they may lead to a significant increase of serum potassium.

Drug/Laboratory Test Interaction: Captopril may cause a false-positive urine test for acetone.

Carcinogenesis, Mutagenesis, and Impairment of Fertility: Two-year studies with doses of 50 to 1350 mg/kg/day in mice and rats failed to show any evidence of carcinogenic potential. Studies in rats have revealed no impairment of fertility.

Usage in Pregnancy: There are no adequate and well-controlled studies in pregnant women. Embryocidal effects were observed in rabbits. Therefore, captopril should be used during pregnancy only if the potential benefit outweighs the potential risk to the fetus.

Nursing Mothers: Captopril is secreted in human milk. Exercise caution when administering captopril to a nursing woman, and, in general, nursing should be interrupted.

Pediatric Use: Safety and effectiveness in children have not been established although there is limited experience with use of captopril in children from 2 months to 15 years of age. Dosage, on a weight basis, was comparable to that used in adults. Captopril should be used in children only if other measures for controlling blood pressure have not been effective.

ADVERSE REACTIONS: Reported incidences are based on clinical trials involving about 4000 patients.

Renal — One to 2 of 100 patients developed proteinuria (see WARNINGS). Renal insufficiency, renal failure, polyuria, oliguria, and urinary frequency in 1 to 2 of 1000 patients.

Hematologic — Neutropenia/agranulocytosis occurred in about 0.3% of captopril treated patients (see WARNINGS). Two of these patients developed sepsis and died.

Dermatologic — Rash (usually mild, maculopapular, rarely urticarial), often with pruritus and sometimes with fever and eosinophilia, in about 10 of 100 patients, usually during the 1st 4 weeks of therapy. Pruritus, without rash, in about 2 of 100 patients. A reversible associated pemphigoid-like lesion, and photosensitivity have also been reported. Angioedema of the face, mucous membranes of the mouth, or of the extremities in about 1 of 100 patients — reversible on discontinuance of captopril therapy. One case of laryngeal edema reported. Flushing or pallor in 2 to 5 of 1000 patients.

Cardiovascular — Hypotension in about 2 of 100 patients. See WARNINGS (Hypotension) and PRECAUTIONS (Drug Interactions) for discussion of hypotension on initiation of captopril therapy. Tachycardia, chest pain, and palpitations each in about 1 of 100 patients. Angina pectoris, myocardial infarction, Raynaud's syndrome, and congestive heart failure each in 2 to 3 of 1000 patients.

Dysgeusia — About 7 of 100 patients developed a diminution or loss of taste perception; taste impairment is reversible and usually self-limited even with continued drug use (2 to 3 months). Gastric irritation, abdominal pain, nausea, vomiting, diarrhea, anorexia, constipation, aphthous ulcers, peptic ulcer, dizziness, headache, malaise, fatigue, insomnia, dry mouth, dyspnea, and paresthesias reported in about 0.5 to 2% of patients but did not appear at increased frequency compared to placebo or other treatments used in controlled trials.

Altered Laboratory Findings: Elevations of liver enzymes in a few patients although no causal relationship has been established. Rarely cholestatic jaundice and hepatocellular injury with secondary cholestasis have been reported. A transient elevation of BUN and serum creatinine may occur, especially in volume-depleted or renovascular hypertensive patients. In instances of rapid reduction of longstanding or severely elevated blood pressure, the glomerular filtration rate may decrease transiently, also resulting in transient rises in serum creatinine and BUN. Small increases in serum potassium concentration frequently occur, especially in patients with renal impairment (see PRECAUTIONS).

OVERDOSAGE: Primary concern in correction of hypotension. Volume expansion with an I.V. infusion of normal saline is the treatment of choice for restoration of blood pressure. Captopril may be removed from the general circulation by hemodialysis.

DOSAGE AND ADMINISTRATION: CAPOTEN should be taken one hour before meals. Dosage must be individualized; see DOSAGE AND ADMINISTRATION section of package insert for detailed information regarding dosage in hypertension and in heart failure. Because CAPOTEN (captopril) is excreted primarily by the kidneys, dosage adjustments are recommended for patients with impaired renal function.

Consult package insert before prescribing CAPOTEN (captopril).

HOW SUPPLIED: Available in tablets of 25, 50, and 100 mg in bottles of 100, and in UNIMATIC® unit-dose packs of 100 tablets.

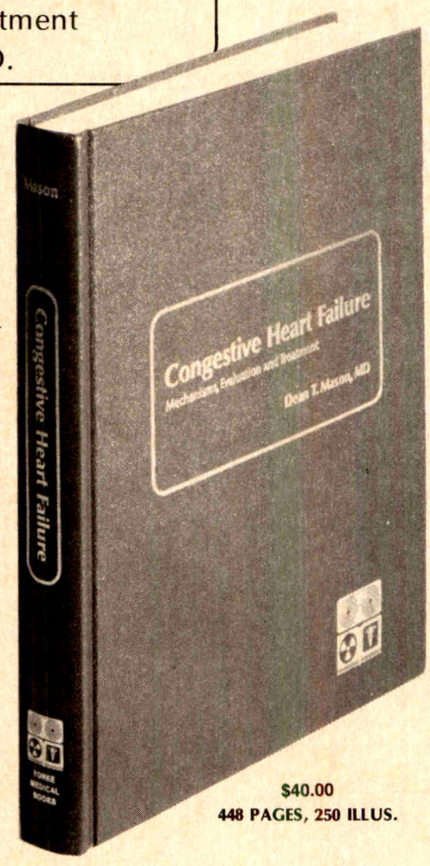
Congestive Heart Failure

Mechanisms, Evaluation and Treatment

Dean T. Mason, M.D.



$40.00
448 PAGES, 250 ILLUS.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis. President, Western Society for Clinical Research

Immediate Past President, American College of Cardiology

Member of the American Board of Internal Medicine Cardiovascular Diseases

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

YORKE MEDICAL BOOKS Box C-757, Brooklyn, N.Y. 11205

Please send me a copy of CONGESTIVE HEART FAILURE for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($40.00) plus shipping cost). Otherwise, the book will be returned for full credit or refund.

☐ Full payment enclosed, publisher absorbs shipping cost.

☐ Send invoice (U.S. and Canada only)

Countries outside Western Hemisphere: $40.00 prepaid in U.S. funds.

New York State residents add applicable sales tax.

Morphologic Features of the Normal and Abnormal Mitral Valve

WILLIAM C. ROBERTS, MD

Anatomic and functional features of the normal and abnormal mitral valve are reviewed. Of 1,010 personally studied necropsy patients with severe (functional class III or IV, New York Heart Association) cardiac dysfunction from primary valvular heart disease, 434 (43%) had mitral stenosis (MS) with or without mitral regurgitation (MR): unassociated with aortic valve stenosis or regurgitation or with tricuspid valve stenosis in 189 (44%) patients, and associated with aortic stenosis in 152 (35%), with pure (no element of stenosis) aortic regurgitation in 65 (15%) patients, and with tricuspid valve stenosis with or without aortic valve stenosis in 28 (6%) patients. The origin of MS was rheumatic in all 434 patients. Of the 1,010 necropsy patients, 165 (16%) had pure MR (papillary muscle dysfunction excluded): unassociated with aortic valve stenosis or regurgitation or with tricuspid valve stenosis in 97 (59%) patients, and associated with pure aortic regurgitation in 45 (27%) and with aortic valve stenosis in 23 (14%) patients. When associated with dysfunction of the aortic valve, pure MR was usually rheumatic in origin, but when unassociated with aortic valve dysfunction it was usually nonrheumatic in origin. Review of operatively excised mitral valves in patients with pure MR unassociated with aortic valve dysfunction disclosed mitral valve prolapse (most likely an inherent congenital defect) as the most common cause of MR. Excluding the patients with MR from coronary heart disease (papillary muscle dysfunction), mitral prolapse was the cause of MR in 60 (88%) of the other 68 patients, and a rheumatic origin was responsible in only 3 of the 68 patients, all 68 of whom were >30 years of age.

Mitral anular calcification in persons aged >65 years is usually associated with calcific deposits in the aortic valve cusps and in the coronary arteries. Because calcium in each of these 3 sites is common in older individuals residing in the Western World, it is most reasonable to view mitral anular calcification in older individuals as a manifestation of atherosclerosis. Mitral anular calcium appears to be extremely uncommon in persons with total serum cholesterol levels <150 mg/dl. Mitral anular calcium may produce mild MR and, if the deposits are heavy enough, MS.

This report reviews anatomic findings in both the normally and abnormally functioning mitral valve. Major attention is directed to anatomic observations which have clinical usefulness. This review focuses primarily on studies carried out in my laboratory during the past 20 years.

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received and accepted December 3, 1982.

Address for reprints: William C. Roberts, MD, Building 10A, Room 3E30, National Institutes of Health, Bethesda, Maryland 20205.

Normal Mitral Valve (Fig. 1)

The mitral valve, in comparison with the semilunar valves, is a complex structure consisting of 4 major components: leaflets, chordae tendineae, papillary muscles, and anulus.[1,2] Unlike the other 3 cardiac valves, each of which has 3 cusps, the mitral valve consists of only 2 *leaflets*. The anterior one has a much longer basal-to-margin length than does the posterior leaflet, but the length of the anular attachment of the posterior leaflet (about 6 cm) is about twice that of the anterior leaflet (about 3 cm) (Fig. 1). Although the basal-to-margin lengths and the lengths of the basal attachments

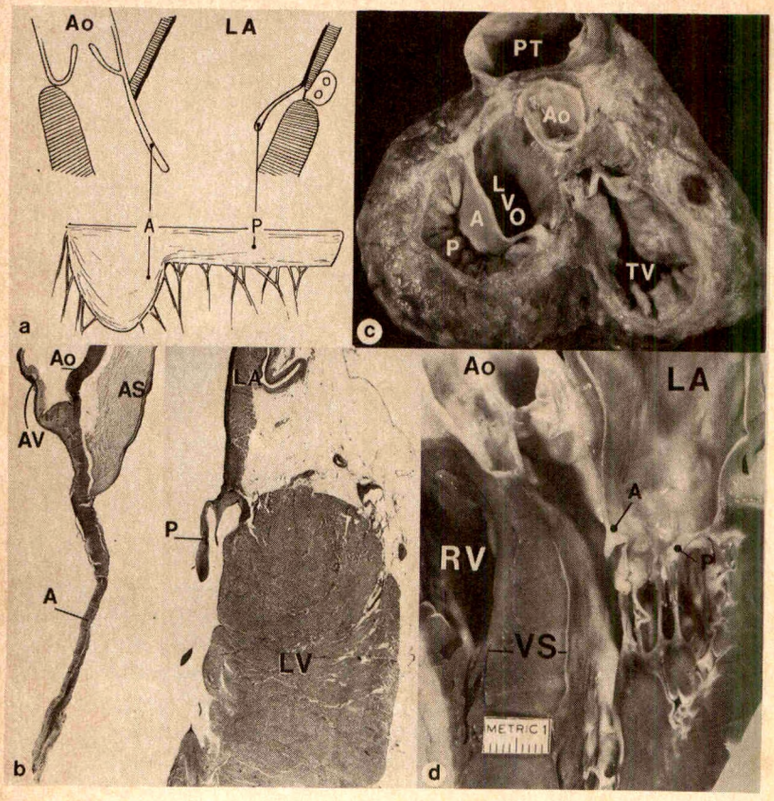

FIGURE 1. Normal mitral valve. **a,** diagram showing relation of anterior (A) and posterior (P) mitral leaflets to one another and to left atrium (LA), aortic valve (AV), and aorta (Ao). The inflow and outflow tracts of the left ventricle are divided by the anterior leaflet. The basal attachment of the posterior leaflet is twice as long as that of the anterior leaflet, although the basal-to-margin length of the anterior leaflet is twice that of the posterior leaflet. **b,** histologic sections of the mitral valve confirming the observations depicted in **a.** One section includes the anterior (A) mitral leaflet, the aortic valve cusp (AV), the wall of the aorta (Ao), and the atrial septal (AS) wall, and the other includes the left atrial and left ventricular free walls with intervening posterior mitral leaflet. (Elastic van Gieson stains; magnification ×4.5 and ×3, reduced 45%). **c,** view of the heart from above after excision of the atria. The anterior (A) mitral leaflet separates the left ventricular inflow from outflow (LVO). PT = pulmonary trunk; TV = tricuspid valve. **d,** longitudinal cut of the left ventricle, mitral valve, aorta, and left atrium, as would be seen by M-mode echocardiogram.

of each mitral leaflet are quite different, the surface area of each leaflet is virtually identical. The posterior leaflet has a true bundle of fibrous tissue (the anulus) separating the myocardium of left atrium from the myocardium of left ventricle. The posterior leaflet, in a large sense, is simply an extension of mural endocardium from the free walls of the left atrium. In contrast to the posterior mitral leaflet, the anterior leaflet does not have a true anulus but is continuous with the wall of the ascending aorta, aortic valve, membraneous ventricular septum, and atrial septum. The area of the leaflets is about 2.5 times that of the area of the mitral orifice at the level of the mitral anulus. In contrast to the semilunar cusps, which are independent or discontinuous of each other, the 2 mitral leaflets are continuous with each other, being connected at the commissures.

Chordae tendineae from both mitral leaflets insert into both papillary muscles. About 5 times as many

AV = aortic valve; MV = mitral valve; TV = tricuspid valve.

* Excludes patients with mitral regurgitation secondary to coronary heart disease (papillary muscle dysfunction), carcinoid heart disease, and hypertrophic cardiomyopathy and those with infective endocarditis limited to 1 or both right-sided cardiac valves. Tricuspid valve regurgitation was present in many patients in most of the 9 functional groups. All patients were in functional class III or IV (New York Heart Association), and more than half had 1 or more cardiac operations.

† In many patients, the aortic valve cusps actually were normal and the regurgitation was the result of disease of the aorta (Marfan and Marfan-like syndromes, syphilis, systemic hypertension, healed aortic dissection).

‡ The hearts in all 1,010 patients were examined and classified by WCR.

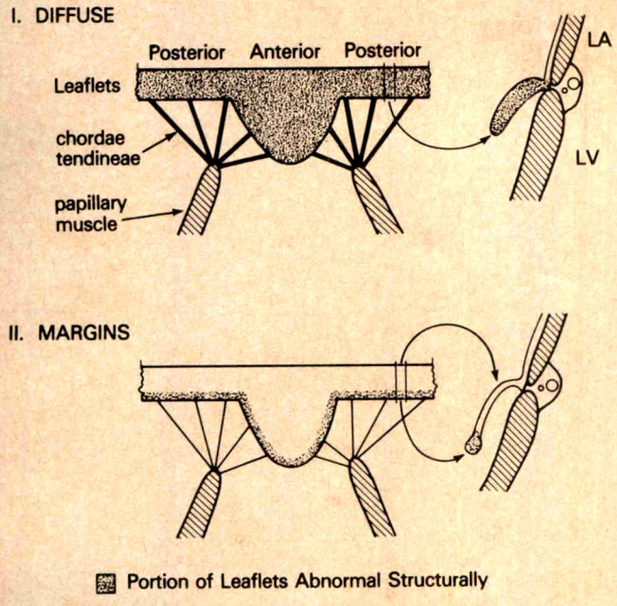

FIGURE 2. Diagram showing the 2 types of anatomic involvement of the mitral valve in rheumatic heart disease. Thickening of chordae are not required for diagnosis, only thickening of the leaflets, either diffusely or on all margins. LA = left atrium; LV = left ventricle. (Reprinted, by permission, from Roberts and Virmani.[11])

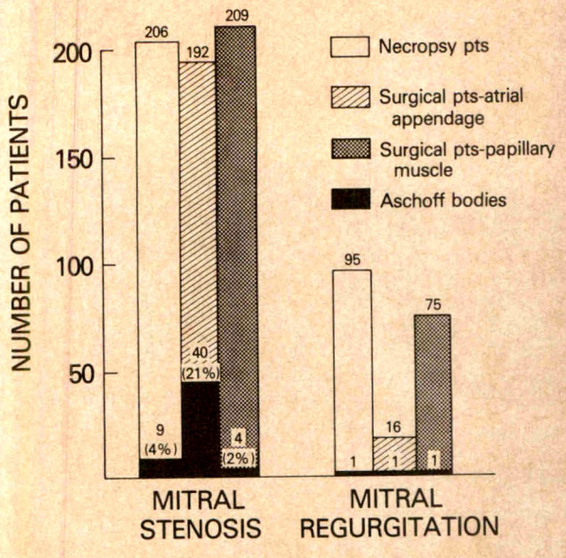

FIGURE 3. Bar graph demonstrating number and percentage of patients (pts) undergoing operations for either mitral stenosis (with or without mitral regurgitation) and pure mitral regurgitation in whom Aschoff bodies were found in either the left atrial appendage or left ventricular papillary muscle.

chordae are attached to leaflets as to papillary muscles. On an average, 24 chordae tendineae are attached to the papillary muscles (12 to each), and 120 chordae are attached to the leaflets.[3] The chordae insert onto the undersurfaces—that is, the ventricular surfaces—of both leaflets. The chordae subdivide as they progress from papillary muscle to leaflet. The subdivisions may be viewed as primary (first order), secondary (second order), and tertiary (third order) chordae. The spaces between the chordae serve as secondary orifices between left atrium and left ventricle. Obviously, the major orifice is the area between the leaflets, but much blood passes between the interchordal spaces. Therefore, fusion of chordae tendineae may narrow the mitral inlet.

The 2 *left ventricular papillary muscles* are preferably designated anterolateral and posteromedial.[3] There is considerable variation in the appearances of these 2 structures in the same person, and comparison of corresponding structures in different persons discloses considerable variation. The anterolateral papillary muscle is generally the more uniform of the 2. It usually consists of a single trunk that protrudes more into the cavity than does the posteromedial one. The posteromedial papillary muscle is generally smaller than the anterolateral structure and often consists of 2 or 3 smaller pillars rather than a single pillar. The posteromedial muscle usually has several connections to the left ventricular wall in addition to the base of the major trunk. Both papillary muscles are attached to the left ventricular free wall roughly at the junction of the caudal third and middle thirds.

With aging, the mitral valve, like other tissues, changes; this change consists mainly of focal fibrous thickening of both leaflets and chordae. The left ventricular cavity becomes smaller (presumably because the cardiac output decreases) as we grow older,[2,4] and consequently less area becomes available in the left ventricle to accommodate the mitral leaflets and chordae. The leaflets then contact one another abnormally during ventricular systole and focal fibrous thickening results. Since the left ventricular cavity diminishes with age, the mitral *anulus* does also. The latter change further increases the abnormal contact of the mitral leaflets with one other and furthers the leaflet scarring. This scarring from aging, however, is not enough to cause mitral dysfunction.

Abnormal Mitral Valve

Mitral Stenosis

The essential hemodynamic fault caused by mitral stenosis (MS) is the inability of the left atrium to empty normally.[2] In sinus rhythm, left atrial contraction serves to augment its emptying, but atrial contraction is lost in atrial fibrillation. The obstruction, represented by a pressure gradient across the valve, results in pulmonary venous obstruction which may be apparent on chest roentgenography.

Of the 9 single or combined cardiac valve lesions severe enough to be fatal, MS, in my experience, ranks second[5,6] (Table I). Of 1,010 patients >14 years of age with functionally severe (class III or IV, New York Heart Association) valvular cardiac disease whom I had studied at necropsy up to 1980, 434 (44%) had MS.[2] Only aortic valve stenosis was more common.[7–9] Mitral

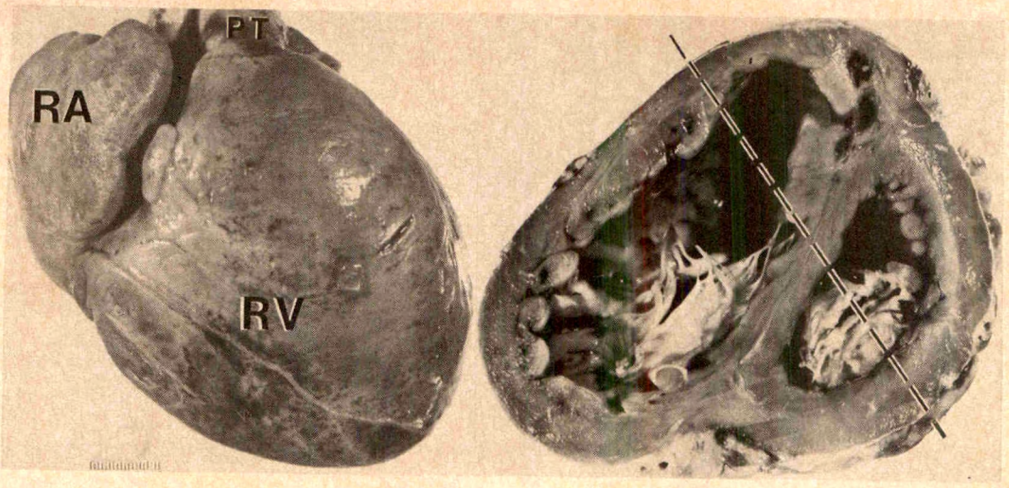

FIGURE 4. Heart in a 16-year-old boy (NIH #A77-232) who had acute rheumatic fever at age 6 years and chronic congestive heart failure beginning at age 10 years. By examination, the patient had evidence of severe mitral stenosis and tricuspid regurgitation. At cardiac catheterization 10 hours before death, the right ventricular pressure was 100/20 and the left ventricular pressure, 100/10 mm Hg. Neither pulmonary arterial wedge or left atrial pressures were obtained. Left ventriculogram disclosed no mitral regurgitation and a normal-sized left ventricular cavity. The patient had acute pulmonary edema after catheterization and underwent closed mitral commissurotomy as a terminal procedure on the ward. At necropsy, the heart weighed 450 g (the patient weighed 43 kg). The right atrium (RA) and ventricle (RV) were huge, and the thickness of the free walls of both ventricles were similar. Both mitral and tricuspid valve leaflets were diffusely thickened but free of calcific deposits. No Aschoff bodies were present. The **dashed straight line** is the line of the M-mode beam. PT = pulmonary trunk.

stenosis occurred alone in 189 (44%) patients and in combination with other functional valvular lesions in the other 245 (56%) patients. Mitral stenosis was rheumatic in origin in all 434 patients.[10,11]

Although a functional classification of valvular heart disease is most useful from physiologic and therapeutic standpoints, an anatomic classification is helpful from an etiologic standpoint. Five anatomic categories have proved useful: isolated mitral, isolated aortic, combined mitral and aortic, combined tricuspid and mitral with

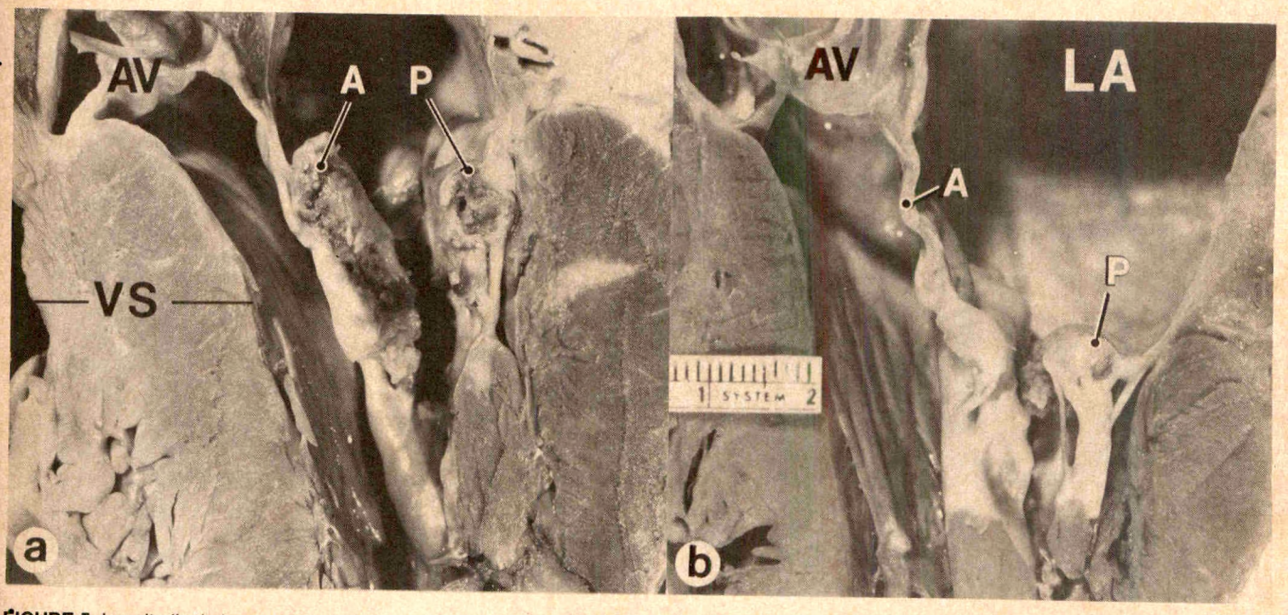

FIGURE 5. Longitudinal views, as would be seen by M-mode echocardiogram, of 2 hearts of patients with severe mitral stenosis. **a,** in a 55-year-old man (GT #74A-69) with equal peak systolic pressures in the right and left ventricles and no associated mitral regurgitation. The patient died from massive bleeding during cannulation of the aorta for planned mitral valve replacement. Both anterior (A) and posterior (P) mitral leaflets are heavily calcified. AV = aortic valve; VS = ventricular septum. **b,** in a 64-year-old woman (GT #78A-129) with right and left ventricular peak systolic pressures of 100 and 135 mm Hg, respectively, and an 18 mm Hg mean diastolic gradient between pulmonary arterial wedge position and left ventricle just before closed mitral commissurotomy 3 years before death. This patient died of progressive congestive cardiac failure. The heart weighed 410 g. The amount of calcium in the thickened mitral leaflets is relatively mild. LA = left atrium.

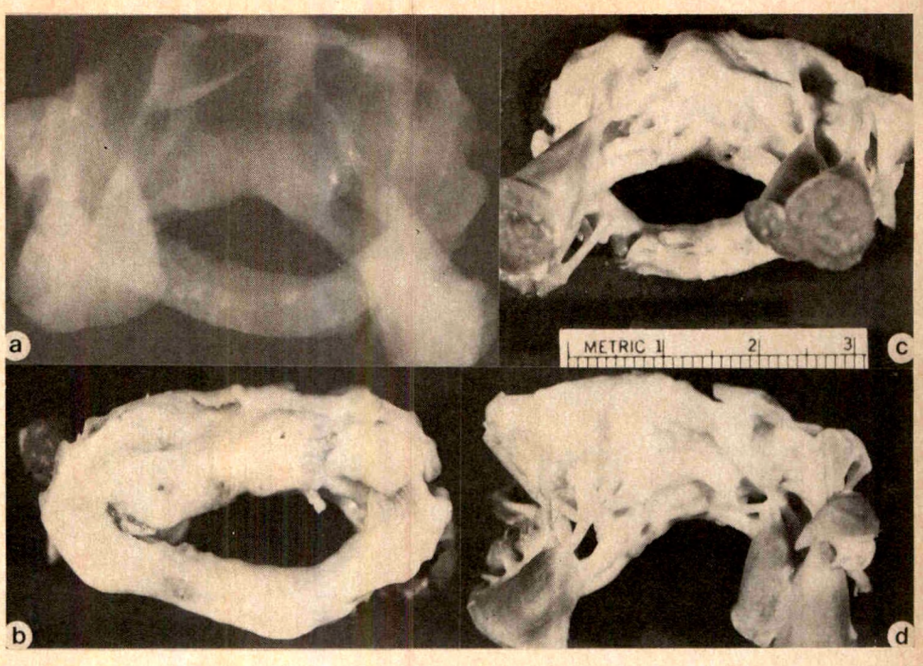

FIGURE 6. Operatively excised stenotic mitral valve in a 40-year-old woman with only a minute calcific deposit in the anterior leaflet. The mean diastolic gradient between the pulmonary arterial wedge position and the left ventricle was 13 mm Hg, the peak pulmonary arterial systolic pressure was 50 mm Hg, and 3+/4+ mitral regurgitation was present by left ventriculogram. **a,** radiogram of operatively excised valve. **b,** view from left atrial aspect. **c,** view from left ventricular aspect. **d,** view of anterior leaflet and papillary muscles. (Reprinted, by permission, from Lachman and Roberts.[18])

or without aortic, and both tricuspid and mitral (Table I). Anatomically isolated aortic valve disease is never rheumatic in origin.[5] Isolated mitral disease causing MS is, with rare exception, rheumatic in origin, but isolated mitral disease causing pure regurgitation is usually nonrheumatic in origin.[12] Anatomic valve disease involving more than 1 cardiac valve is usually rheumatic in origin. Isolated anatomic disease of the tricuspid or pulmonic valves, or both, is usually congenital or infectious in origin or is associated with the carcinoid syndrome.[13–17]

A valve may function normally and yet be anatomically abnormal. Only 62% of the 189 patients with isolated MS (with or without mitral regurgitation [MR]) had anatomic involvement limited to the mitral valve[6] (Table I). In contrast, 88% of the 292 patients with clinically isolated aortic valve stenosis (with or without regurgitation) had anatomic disease limited to the aortic valve only.

Rheumatic heart disease may be viewed as a disease of the mitral valve; other valves also may be involved both anatomically and functionally, but anatomically the mitral valve is always involved[11] (Fig. 2). To my knowledge, *Aschoff bodies* have never been found in hearts without anatomic disease of the mitral valve.[11] Of the first 543 patients with severe valvular heart disease whom I studied at necropsy, 11 (27%) had Aschoff bodies, and all had anatomic mitral valve disease. The ages of the 11 patients with Aschoff bodies ranged from 18 to 68 years (mean 38) and 9 had a history of acute rheumatic fever earlier in life. Clinical study revealed that 9 of the 11 patients had MS with or without dysfunction of 1 or more other cardiac valves, 1 had isolated pure aortic regurgitation, and 1 had both mitral and aortic regurgitation. All 11 patients had diffuse fibrous thickening of the mitral valve leaflets and all but 1 had diffuse anatomic lesions of at least 2 other cardiac valves. No patient with anatomic lesions limited to the aortic valve had Aschoff bodies. Thus, among patients with chronic valvular heart disease, Aschoff bodies, the only anatomic lesion pathognomonic of rheumatic heart disease, usually indicate diffuse anatomic lesions of 1 or more other cardiac valves. The functional mitral lesion is usually stenosis.

Although they are rare at necropsy in patients with fatal chronic valvular heart disease, Aschoff bodies are fairly common in the heart in patients having mitral valve commissurotomy for MS.[10] Among 481 patients undergoing various mitral valve operations, Aschoff bodies were found in 40 (21%) of 191 operatively excised left atrial appendages, in 4 (2%) of 273 operatively excised left ventricular papillary muscles (1 per patient), and in 1 (6%) of 17 patients with both left atrial appendage and papillary muscle operatively excised (Fig. 3). Of the 45 patients with Aschoff bodies, 44 had MS preoperatively, and only 1, a 10-year-old boy, had pure MR. Sinus rhythm was present in 38 (84%), and atrial fibrillation in 7 (16%). Perioperatively, only 1 of the 45 patients with Aschoff bodies had clinical or laboratory stigmata compatible with acute rheumatic fever, and 58% had an illness compatible with acute rheumatic fever at any time.

Rheumatic heart disease not only is a disorder of the cardiac valves; it also affects mural endocardium, pericardium, and myocardium. On histologic study, the atrial walls virtually always have increased amounts of fibrous tissue in both myocardial interstitium and in the mural endocardium, atrophy of some and hypertrophy of other myocardial cells, and hypertrophy of smooth muscle cells of the mural endocardium. In all patients with rheumatic MS, the leaflets are diffusely thickened, either by fibrous tissue or calcific deposits or both; the

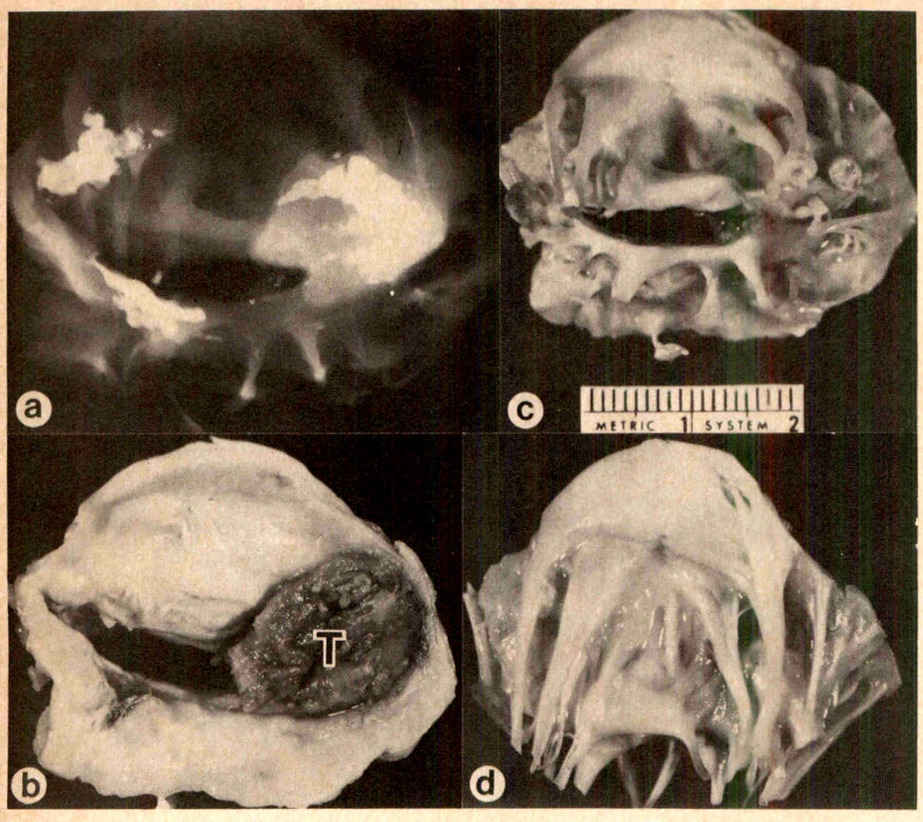

FIGURE 7. Operatively excised stenotic mitral valve in a 72-year-old woman (S76-76) who had had an embolus to a femoral artery 5 years earlier. **a,** radiogram of the operatively excised valve showing focal calcific deposits. **b,** view of the valve from the left atrial aspect showing an oval thrombus (T) over half of the orifice. No thrombus was present in the left atrial cavity. **c,** view of the valve from the left ventricular aspect. The orifice is eccentric. **d,** view of the anterior leaflet.

commissures are usually fused, and the chordae tendineae are shortened and usually fused to some degree (Fig. 4 to 8). The great obstruction to this funnel-shaped valve occurs at its apex, which is within the left ventricular cavity. The primary orifice, located at the level of the anulus, is far less narrowed. Fusion may involve 1 or both commissures. When only 1 is fused or 1 is fused more than the other, the stenotic orifice is eccentrically located. A centrally located orifice indicates symmetrical commissural fusion. In rheumatic MS, the chordae tendineae are occasionally so retracted that the leaflets appear to insert directly into the papillary muscles. When this occurs, the MS is always severe because the interchordal spaces are almost entirely obliterated. Sometimes chordae inserting into 1 papillary muscle are well preserved, whereas those inserting into the other papillary muscle are partially or completely fused. Mitral commissurotomy on a valve in which the leaflets insert almost directly into the papillary muscle(s) usually must include a splitting of the papillary muscle(s) as well as the commissure(s). If there are normally about 120 third-order chordae and about 24 first-order chordae, in MS these numbers are usually halved and, on occasion, even reduced to just 1.

The amount of *calcium* in the leaflets of stenotic mitral valves varies considerably[18] (Figs. 6 to 8). Generally, calcium is more frequent and in larger quantity in men than in women, in older than in younger patients, and in patients with higher compared with those with lower pressure gradients between left atrium and left ventricle[18] (Fig. 9). The rapidity with which calcium develops also varies considerably; it is present at a younger age in men than in women.[18] Lachman and I[18] determined the presence or absence and the extent of calcific deposits in operatively excised stenotic mitral valves by radiography of the excised valve in 164 patients aged 26 to 72 years. The extent of the mitral calcific deposits was determined by the percentage of the valvular circumference containing the deposits: grade 0 (14 patients); grade I = 1 to 25% (43 patients); grade II = 26 to 50% (34 patients); grade III = 51 to 75% (39 patients); and grade IV = 76 to 100% (34 patients). The amount of calcific deposits in the stenotic mitral valves correlated with *sex* and with the *mean diastolic pressure gradient across the mitral valve* ($p < 0.05$) (Fig. 9), but it did not correlate with the patient's age (after age 25 years), cardiac rhythm, pulmonary arterial or pulmonary arterial wedge pressure, previous mitral commissurotomy, presence of thrombus in the body of left atrium, or the presence of disease of 1 or more other cardiac valves.

Among the 164 patients with MS having mitral valve replacement and roentgenography of the excised mitral valve, 14 had no mitral calcium and 43 had only trace or minimal mitral calcific deposits. Thus, we[19] wondered why these 57 patients had mitral replacement rather than mitral commissurotomy. Of the 57 patients, 37 had moderate to severe MR and, therefore, clearly deserved mitral valve replacement. The remaining 20 had absent or minimal calcific deposits, but, nevertheless, they too

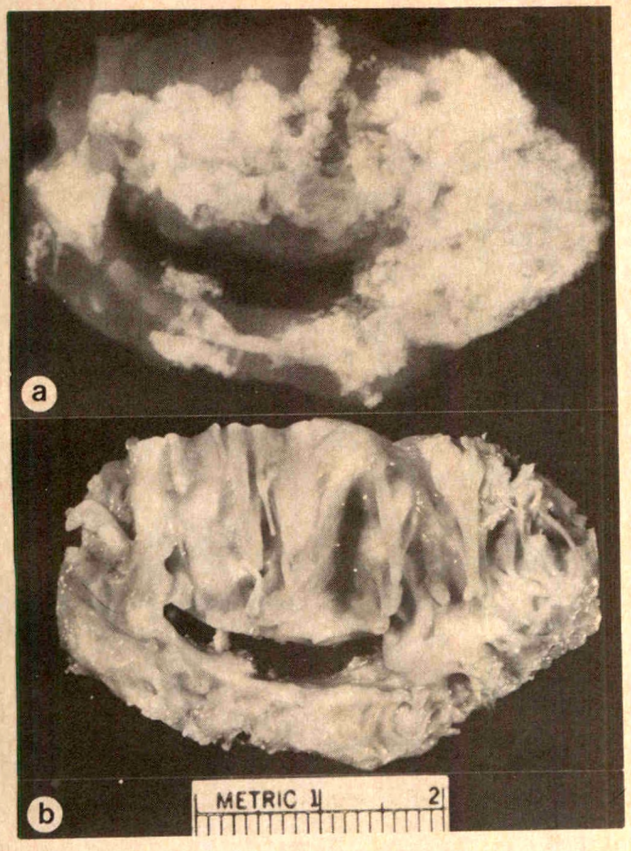

FIGURE 8. Operatively excised stenotic heavily calcified mitral valve in a 53-year-old woman (S67-867) in whom the mean diastolic gradient between the pulmonary arterial wedge position and the left ventricle was 26 mm Hg. She also had 1+/4+ mitral regurgitation by left ventriculogram; a thrombus was present in the body of left atrium. **a,** radiogram of the operatively excised valve. **b,** view of the valve from the left ventricle after excision of the papillary muscle. The orifice is eccentric. (Reprinted, by permission, from Lachman and Roberts.[18])

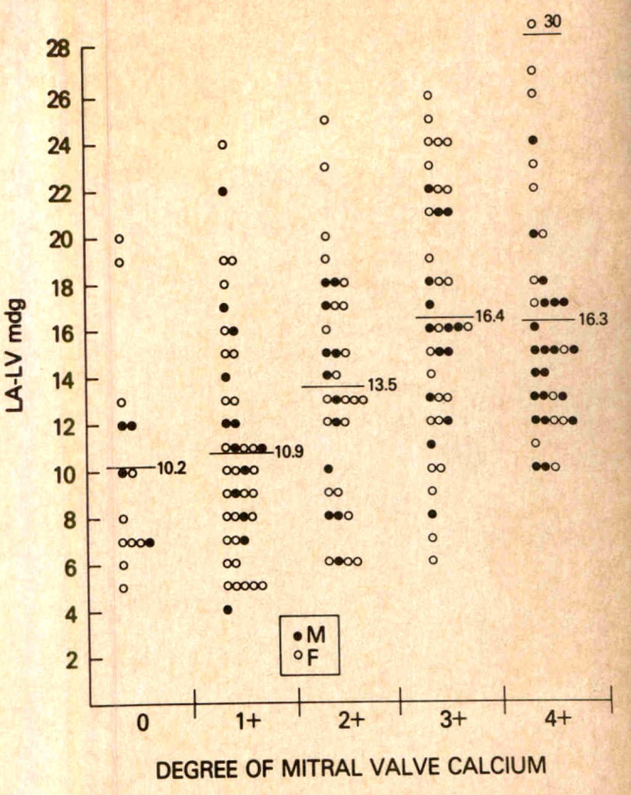

FIGURE 9. Relation between the left atrial (LA) left ventricular (LV) mean diastolic gradient (mdg) and degree of mitral valve calcium. (Reprinted, by permission, from Lachman and Roberts.[18])

had mitral valve replacement. Although in the prevalve replacement era all 20 patients almost surely would have been considered good or ideal candidates for mitral commissurotomy, other factors swung the surgeon to valve replacement rather than commissurotomy. These factors included the need to replace 1 or more other cardiac valves (13 patients), the utilization of cardiopulmonary bypass allowing visual inspection rather than simple palpation of the diseased mitral valve (all 20 patients), relatively little experience with mitral commissurotomy in 4 of the 5 surgeons (17 patients), displeasure with attempted commissurotomy (3 patients), previous mitral commissurotomy (11 patients), and incorrect identification of mitral calcific deposits (2 patients). Even though mitral commissurotomy has been in use for 30 years, the mere alternative of valve replacement may have altered the definition of the stenotic mitral valve previously considered ideal for mitral commissurotomy.

A major complication of MS is *thrombus formation in the left atrial cavity.* The thrombus may be limited to atrial appendage (most common) or be located in both left atrial appendage and body (Fig. 10). The latter group hereafter will be referred to as "left atrial body thrombus." Left atrial body thrombus was observed in 5% of 1,010 personally studied necropsy patients with fatal valvular heart disease; all had severe MS (Table I). Left atrial body thrombus was not observed in any of the 165 patients with pure MR with or without aortic valve dysfunction. All patients with left atrial body thrombi had atrial fibrillation. Comparison of these necropsy patients with 46 patients with MS operated upon at the National Heart, Lung, and Blood Institute and in whom thrombus was found at operation in the left atrial body disclosed that 42 (91%) patients had atrial fibrillation. In contrast, of 40 living patients undergoing mitral valve replacement for pure MR and operated upon at the National Heart, Lung, and Blood Institute, none had thrombus in the body of the left atrium, although 75% had atrial fibrillation. *Thrombus appears to occur in the body of the left atrium only in patients with MS, and atrial fibrillation without MS is incapable of forming a thrombus in the left atrial body.*

Calcific deposits on the mural endocardium of the left atrium are indicative of previous organization with calcification of left atrial thrombi. Histologically, the "calcific thrombi" also contain cholesterol clefts and are identical to atherosclerotic plaques. The observation that left atrial thrombi can organize into lesions iden-

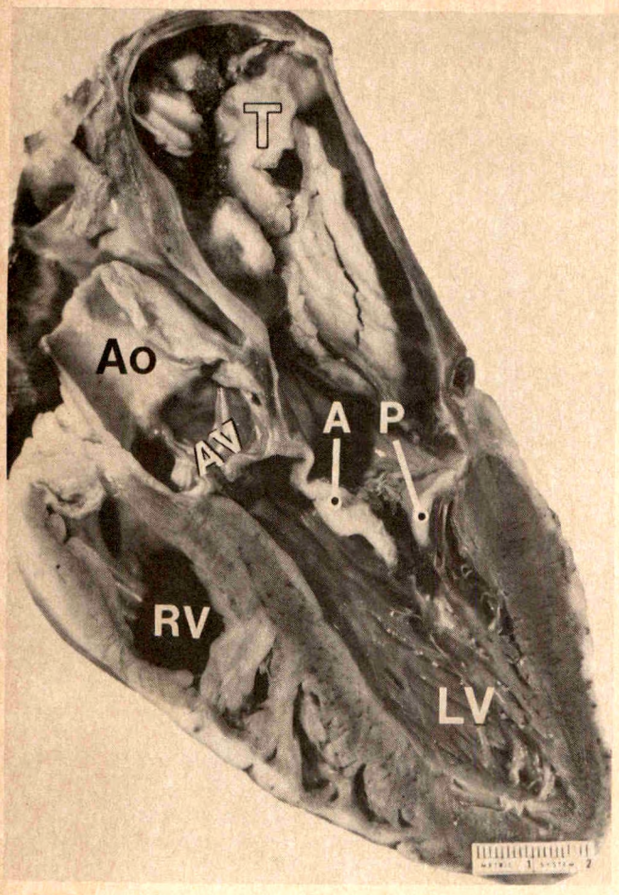

FIGURE 10. Long-axis view of the heart in a 53-year-old woman (GT#77A-190) in whom a huge thrombus (T) was found in the body of the left atrium at necropsy. The mitral valve is quite stenotic. The aortic valve (AV) is normal. A = anterior and P = posterior mitral leaflet; Ao = aorta; LV = left ventricle; RV = right ventricle. Mitral valve commissurotomy had been recommended when the patient was 40 years of age, but she declined. Her last 2 years were characterized by chronic progressive congestive cardiac failure complicated by anemia from multiple myeloma. The patient had chronic atrial fibrillation, but never had cardiac catheterization, a cardiac operation, or evidence of systemic emboli.

tical to atherosclerotic plaques supports the view that atherosclerotic plaques may be the result of organization of thrombi. If calcific deposits form on left atrial body endocardium before the left atrial cavity has had time to dilate, this cavity may be prevented thereafter from dilating. The elevated left atrial pressure may lead more rapidly to pulmonary venous, pulmonary arterial, and right ventricular dilatation with subsequent tricuspsid regurgitation and development of huge right atrial dilatation.[20]

Nonrheumatic causes of MS include *congenital anomalies*[21] (Fig. 11); *neoplasms* (Fig. 12) (particularly myxoma[22]) protruding through the mitral orifice from the left atrium (but malignant neoplasms primary or secondary in the lung may grow into the mitral orifice by way of the pulmonary veins[23]); *large vegetations from active infective endocarditis*[24,25]; and *massive mitral anular calcific deposits*, particularly when associated with small-sized left ventricular cavities and left ventricular outflow tract obstruction[26] (Fig. 13). A relatively new, acquired cause of MS is a *mechanical prosthetic or bioprosthetic cardiac valve.*[27–29] Since the native mitral valve is within the left ventricle, a prosthetic mitral valve also is located within this cavity. The prosthesis must be small enough for the contracting left ventricular wall not to interfere with movement of the prosthetic poppet or disk. When the prosthesis is too large for the cavity into which it was inserted, the poppet may be prevented from moving adequately and may therefore obstruct left atrial emptying. The latter state is far more common than obstruction to left ventricular emptying by the prosthesis. Thrombus formation on a mitral prosthesis also may obstruct left atrial emptying.

Pure Mitral Regurgitation

In contrast to MS, which has mainly 1 cause (rheumatic), pure MR has numerous causes.[2,3,12,16,17,23,30–60] Of the 1,010 patients with functionally severe valvular heart disease, excluding papillary muscle dysfunction, studied personally at necropsy, 165 (16%) had pure (no element of stenosis) MR[5] (Table I); the MR was isolated in 97 of these patients (59%) and associated with aortic valve dysfunction in 68 (41%) (aortic regurgitation in 45 and aortic stenosis in 23). In the 68 patients with associated aortic valve dysfunction, the origin of the valvular disease was rheumatic. Of the 97 patients with clinically isolated pure MR, the aortic valve or the tricuspid valve or both was anatomically abnormal (mild diffuse scarring) in 12 and therefore the cause of the mitral valve dysfunction in these patients was also rheumatic in origin (Table I). Of the remaining 85 patients, the origin of the pure MR was usually nonrheumatic, most commonly ruptured chordae tendineae from infection on a previously normal valve or spontaneous rupture with underlying prolapsing (or floppy) mitral leaflet(s).

Why the mitral valve affected by acute rheumatic fever becomes stenotic in some patients and purely regurgitant in others (mainly children) is unknown. Although the cause may be similar (rheumatic), the structural alterations in the purely regurgitant mitral valve are quite different from those in the stenotic valve. The purely regurgitant rheumatic valve infrequently contains calcific deposits, its commissures are virtually never fused, and its chordae tendineae are only mildly thickened, if at all; chordal fusion is infrequent (Fig. 14). It is often difficult to explain adequately the mechanism of MR in a valve made purely regurgitant by consequences of rheumatic fever. The mitral anuli in children with rheumatic MR usually are dilated but this mechanism is most often not applicable in adults with rheumatic MR.

Rheumatic disease is never limited to endocardium. Inflammatory cells are nearly always found in atrial walls of patients dying with acute rheumatic fever.[61] The inflammation appears to weaken the walls, and superimposed MR tends to dilate the chamber out of proportion to the dilation that would occur with similar degrees of MR into a left atrium with previously normal

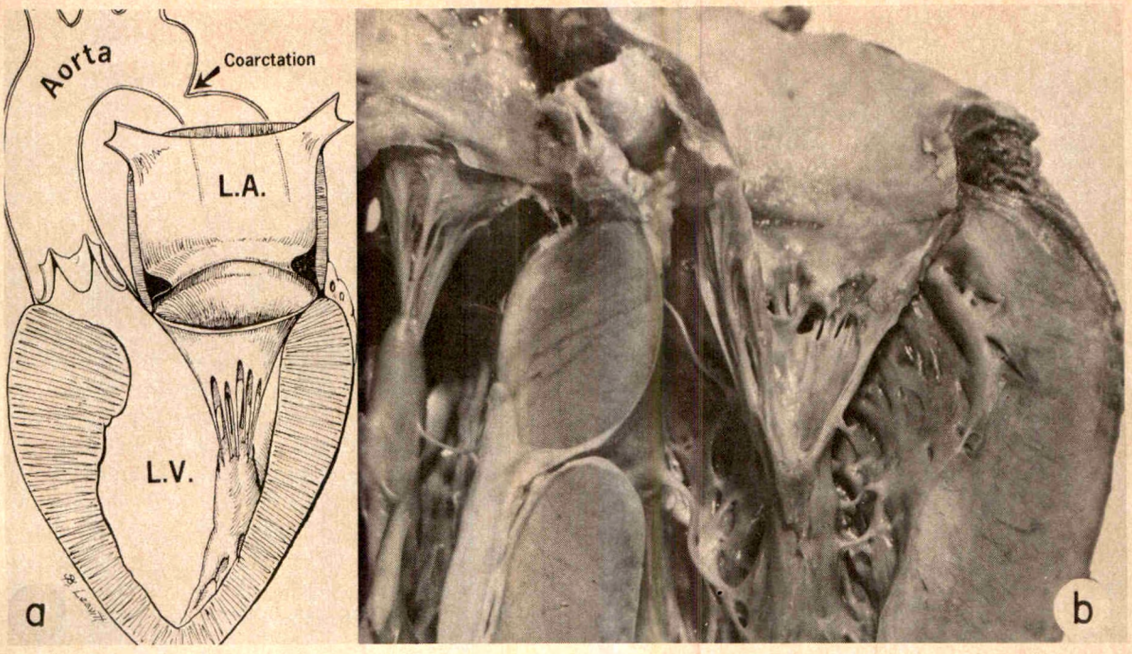

FIGURE 11. Parachute mitral valve causing mitral stenosis in a 14-year-old boy (GT #71A-215) who presented clinically with signs of left ventricular outflow obstruction. The peak systolic gradient between the left ventricle (L.V.) and a systemic artery was 80 mm Hg. Obstruction was caused by a small aortic "anulus" with a bicuspid aortic valve and by discrete obstruction just below the aortic valve. At necropsy, the mitral valve showed a parachute configuration, and all of its chordae inserted into a single left ventricular papillary muscle. Preoperatively, the left atrial mean pressure was 30 mm Hg, and the pulmonary arterial systolic pressure was 50 mm Hg. It was not realized while the patient was alive, however, that the mitral valve was stenotic. In addition, a functionally insignificant coarctation of the aorta was present. A ventricular septal defect had closed spontaneously. L.A. = left atrium. (Reprinted, by permission, from Roberts and Cohen.[3])

walls.[41] What causes the left atrium to dilate enormously in some patients with rheumatic MR is uncertain. Possibly, the patients with so-called giant atria have had more frequent or more severe attacks of acute rheumatic fever, with particularly severe destruction of atrial myocardial fibers. When the left atrium in pure MR is giant in size (Fig. 15), intimal proliferation is rarely found in the pulmonary veins or arteries, and the right ventricular walls are not hypertrophied.[41,47] The larger the left atrial cavity in pure MR, the lower its intracavity pressure. Since the right ventricular walls in these patients are usually not hypertrophied (because the right ventricular systolic pressures are normal or near normal), tricuspid regurgitation is infrequent. In contrast, patients with large left atria from MS or from combined MS and MR have elevated left atrial, pulmonary venous, pulmonary arterial, and right ventricular pressures; the right ventricular walls therefore are

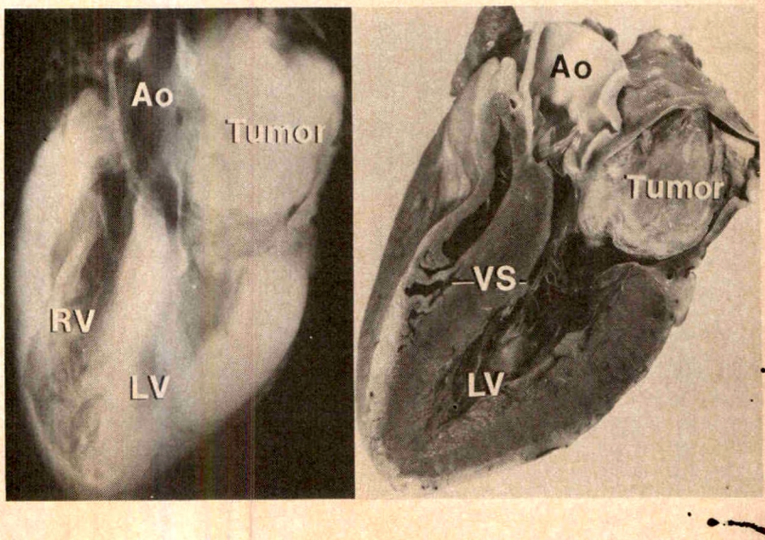

FIGURE 12. Metastatic ovarian carcinoma to the lung with extension into the pulmonary veins and from there into the left atrial body to partly obstruct the mitral orifice in a 44-year-old woman (NNMC #A76-150) who had been asymptomatic until 6 weeks before death, when evidence of congestive heart failure appeared. A precordial murmur was not recorded. **a,** radiogram of heart at necropsy showing a mass in the left atrium and **b,** a long-axis view of heart. Ao = aorta; LV = left ventricle; RV = right ventricle; VS = ventricular septum.

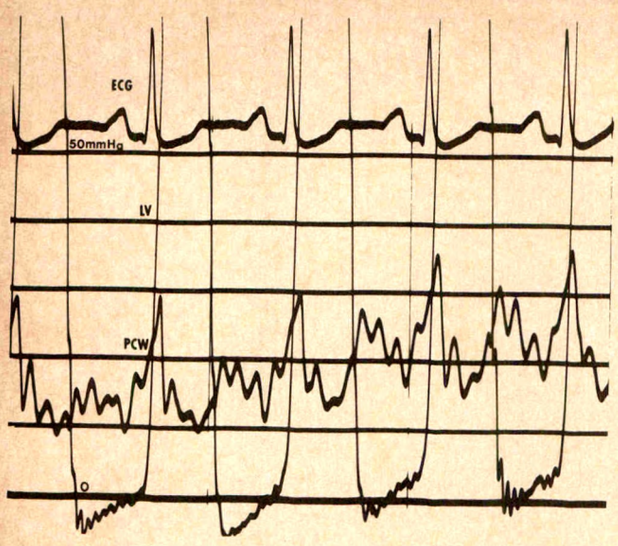

FIGURE 13. Simultaneous, equisensitive recording of pulmonary arterial wedge (PCW) and left ventricular (LV) pressures in a 70-year-old woman (GT #74A-287) with severe (153 mm Hg peak systolic gradient) aortic valve stenosis and massive (4+/4+) mitral anular calcium producing a 15 mm Hg mean diastolic pressure gradient at the level of the otherwise anatomically normal mitral valve. Thus, heavy mitral anular calcific deposits in the setting of left ventricular outflow obstruction can produce "mitral stenosis." ECG = electrocardiogram. (Reprinted, by permission, from Hammer et al.[26])

hypertrophied. Thus, tricuspid regurgitation is a common consequence.

Rupture of mitral chordae tendineae is another common cause of fatal or potentially fatal pure MR.[41,42] The normal chordae tendineae are the ones most likely to rupture, not the previously thickened ones. Thus, rupture of 1 or several thick chordae tendineae in patients with MS is extremely rare. The cause of the rupture varies. Infective endocarditis is the most common cause of acute rupture[41] (Fig. 16). Of 42 patients with healed ruptured mitral chordae tendineae studied by Buchbinder and me, however, only 14 had had infective endocarditis. Infective endocarditis causes acute severe MR by chordal rupture and rarely by leaflet perforation[16] (Fig. 17). The syndrome of acute severe MR associated with normal- or near-normal–sized left atria and severe elevations of left atrial, pulmonary venous, pulmonary arterial, and right ventricular pressures is usually the result of rupture of chordae tendineae by infective endocarditis involving previously normal valves[41] (Fig. 18). The left atrial myocardial fibers in these patients, as contrasted to those in patients with chronic rheumatic MR, have not been previously damaged by rheumatic fever, and, therefore, the left atrial wall is capable of responding to the sudden elevation of left atrial pressure by vigorous contractions, leading to myofiber hypertrophy. The ventricular sys-

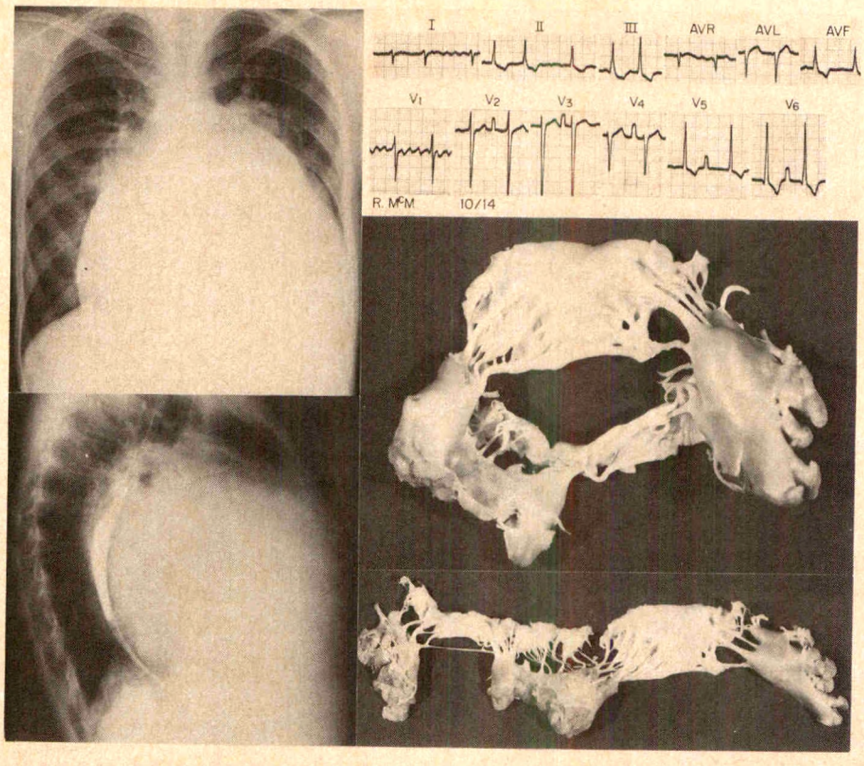

FIGURE 14. Pure mitral and tricuspid valve regurgitation of rheumatic origin in a 15-year-old girl (A63-230) who died 2 days after mitral valve replacement. Shown are posteroanterior and lateral radiograms and an electrocardiogram immediately preoperatively and the intact and opened operatively excised mitral valve. The patient had acute rheumatic fever at ages 6 and 8 years and a prominent "malar flush." The right ventricular and femoral arterial peak systolic pressures were 70 and 110 mm Hg, respectively, preoperatively. The mitral leaflets are diffusely thickened but only mildly so. No Aschoff bodies were present.

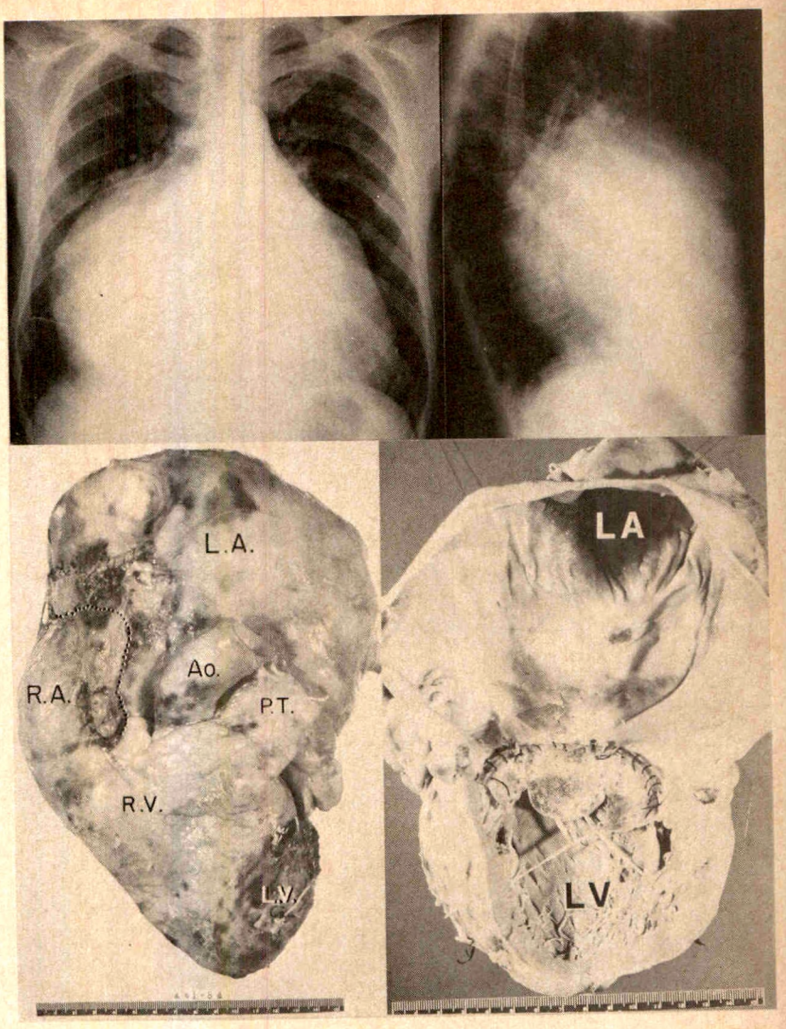

FIGURE 15. Giant-sized left atrium (LA) in a 49-year-old man (A61-84) with severe mitral regurgitation combined with mitral stenosis of rheumatic origin. The right and left ventricular peak systolic pressures were 30 and 100 mm Hg, respectively. The left atrium was entered by a needle inserted into the right mid-axillary line. The patient died 6 hours after mitral replacement. **Lower left,** the giant-sized left atrium is apparent. The **dotted line** outlines the right atrium (RA). Ao = aorta; LV = left ventricle; PT = pulmonary trunk; RV = right ventricle. **Lower right,** opened left atrium, mitral valve, and left ventricle (LV). The ruler units are in centimeters.

tolic pressures in these patients are reflected quickly into the vasculature of the lungs, and severe medial and intimal thickening of the pulmonary arteries and veins progress rapidly. The already diseased left atrium, in contrast, appears to respond to volume load by dilating, not by contracting. Thus, the smaller the left atrial cavity in pure MR, the thicker the right ventricular wall, and, conversely, the larger the left atrial cavity, the thinner the right ventricular wall[41] (Fig. 18).

A relatively new cause of acquired pure MR is *fistulas around the bases of prosthetic and bioprosthetic valves.*[29] Small peribasilar leaks around mitral prostheses are difficult to diagnose clinically without injecting contrast material into the left ventricle.

Although for years rheumatic heart disease has been considered the major cause of significant MR, most patients with rheumatic heart disease and MR also have some degree of MS as well. Of patients with *isolated* (aortic valve function normal), *pure* (no element of stenosis) MR severe enough to warrant mitral valve replacement, *mitral valve prolapse* is now recognized as the most common etiology (Fig. 19 to 22). My associates and I[12] recently reviewed the records and operatively excised mitral valves of 97 patients aged 32 to 78 years (mean 54) (57 men), who underwent mitral valve replacement because of $3^+/4^+$ or $4^+/4^+$ MR as determined by left ventricular angiography. Of the 97 patients, the cause of the MR was leaflet prolapse in 60 (62%), papillary muscle dysfunction from coronary heart disease in 29 (30%), infective endocarditis involving apparently previously normal mitral valve in 5 patients, and rheumatic heart disease in 3 patients (Fig. 23). Of the 60 patients with mitral prolapse, 13 had ruptured chordae tendineae and all 5 patients with infective endocarditis had ruptured chordae.

The circumference of the mitral anuli in the patients with prolapsed valves without ruptured chordae was significantly larger than those in the patients in other groups and in 18 control subjects, both of which were normal (Fig. 24 and 25). Likewise, the areas of the excised leaflets in the prolapsed valves were much larger than in the other groups and in the control subjects, both of which were normal (Fig. 26). The product of the circumference (in centimeters) multiplied by the area (in centimeters squared) calculated for the normal valves ranged from 45 to 140 cm^3 (average 91). The av-

erage product was 150 cm^3 in the prolapsed valves with ruptured chordae, and 273 cm^3 in the prolapsed valves with intact chordae. The products were 87, 93, and 106 cm^3, respectively, in the valves regurgitant because of papillary muscle dysfunction, infective endocarditis, or rheumatic disease; these products did not differ from those of the normal valves.

The correct cause of the MR in the 97 patients was usually predictable from the history alone. Of the 29 patients with papillary muscle dysfunction from atherosclerotic coronary heart disease, all had clinical evidence of myocardial ischemia: history of acute myocardial infarction which had healed in 24, a left ventricular aneurysm from a silent infarction in 1, and angina pectoris in 4. Of the 5 patients with MR secondary to infective endocarditis, 4 had well-documented episodes of infection that had been cured by antibiotic therapy; none had evidence of valvular dysfunction before the episode of infective endocarditis. Of the 3 patients with MR secondary to a rheumatic origin, 2 had a history of acute rheumatic fever, whereas this item was positive in only 5 of the other 94 patients. Clinical diagnosis of mitral valve prolapse was by a process of exclusion. Only 2 (3%) of the 60 patients had historical evidence of previous acute myocardial infarction; 5 (8%) had a history of acute rheumatic fever and 4 (7%) had a history of active infective endocarditis. Compared with the 5 patients classified as having ruptured chordae tendineae on previously normal valves (4 of whom had a history of infective endocarditis), the 4 patients with healed infective endocarditis and mitral prolapse were older (mean age 61 years versus 42 years), had previous systolic murmurs of MR before the episode of infective endocarditis (4 of 4 versus 0 of 5), and had a longer mean duration of congestive heart failure (11 months versus 4 months). Thus, of the 60 patients with prolapse, 51 (85%) had no historical evidence of myocardial ischemia, acute rheumatic fever, or infective endocarditis.

The origin of the MR also was suggested preoperatively by more objective means. All 29 patients with MR secondary to coronary disease had abnormal Q waves by electrocardiogram, whereas abnormal Q waves were present in only 4 of the 60 patients with mitral prolapse and in none of the 8 patients with MR from either in-

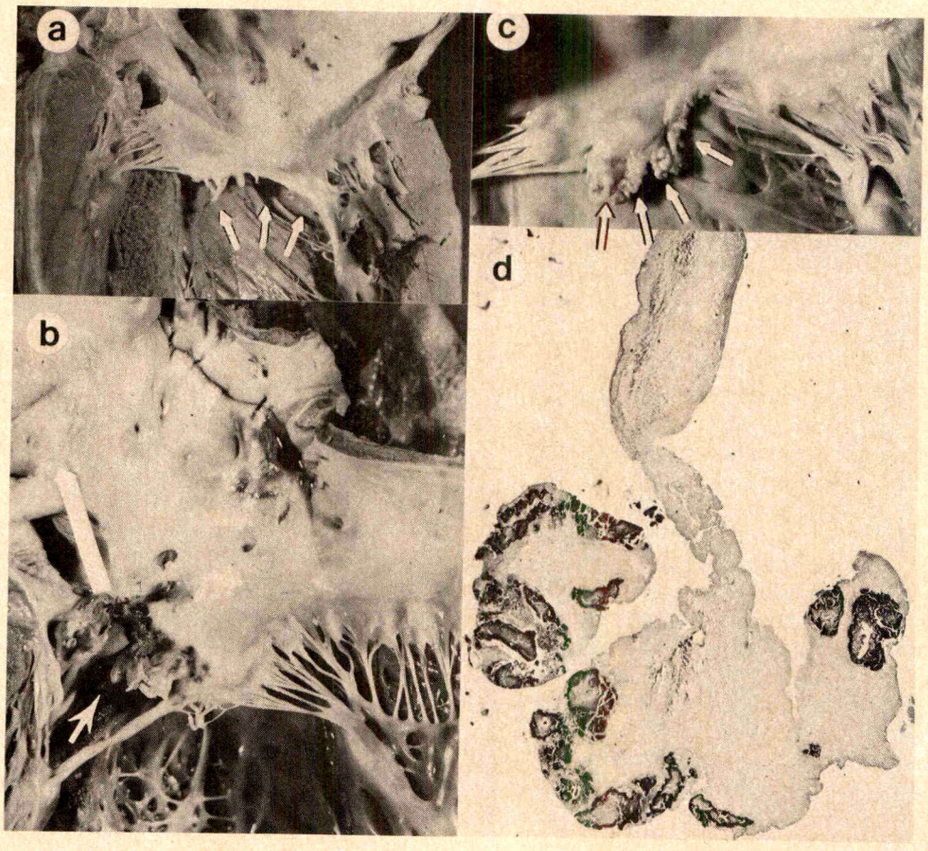

FIGURE 16. Ruptured mitral chordae tendineae (**short arrows**) in 3 patients: **a,** in a 29-year-old woman (A63-97) who had had Staphylococcus epidermidis endocarditis 5 years earlier on what appears to have been a previously anatomically normal valve. The peak systolic pulmonary arterial pressure was 105 mm Hg and the left atrial V wave, 35 mm Hg. **b,** in a 19-year-old girl (A61-221) who had had Streptococcus group D endocarditis 16 months earlier. The peak systolic pulmonary arterial pressure was 70 mm Hg and the left atrial V wave, 36 mm Hg. **c** and **d,** in a 24-year-old woman (A62-19) who had had enterococcus endocarditis 5 months earlier. The peak systolic pulmonary arterial pressure was 72 mm Hg and the left atrial V wave, 66 mm Hg. **d,** histologic section of mitral leaflet at site of chordal rupture showing calcific deposits. fective endocarditis or rheumatic disease. Atrial fibrillation was significantly ($p < 0.05$) more common in the patients in whom the MR resulted from coronary disease: in 7 (24%) of these 29 patients, in only 4 (7%) of the 60 patients with mitral prolapse, and in 2 of the 8 patients with either infective endocarditis or a rheumatic origin. Of the 60 patients with prolapse, 43 had M-mode echocardiograms; in 32 (74%) prolapse was demonstrated. Of the 29 patients with coronary heart disease, M-mode echocardiograms were done in 22; only 2 (9%) demonstrated prolapse. Of the 8 patients with MR from infective endocarditis or rheumatic etiologies, 7 had

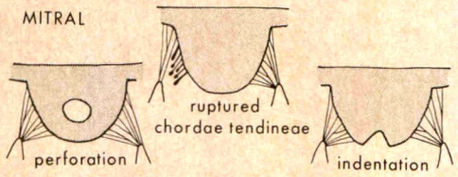

FIGURE 17. Types of mitral valve damage resulting from infective endocarditis.

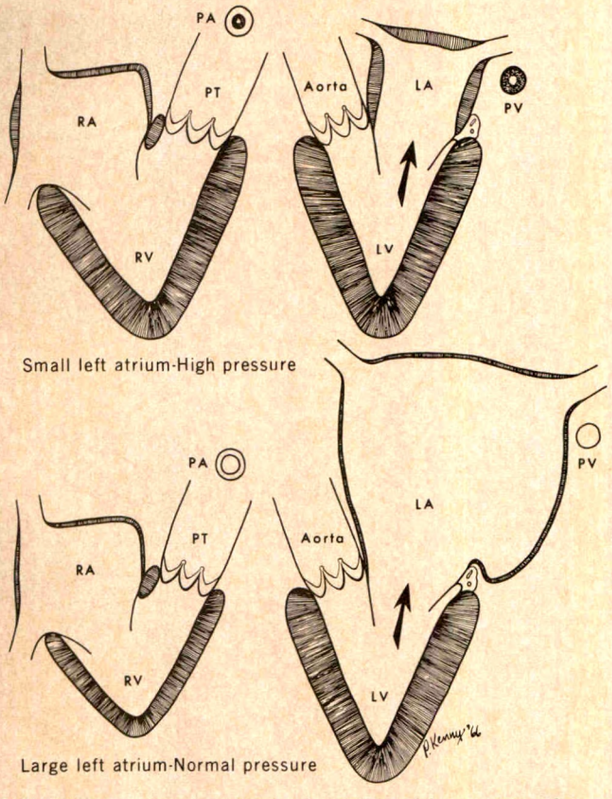

FIGURE 18. Diagram depicting the 2 extremes of the spectrum of pure mitral regurgitation. When severe mitral regurgitation appears suddenly in individuals with previously normal or near-normal hearts, the left atrium (LA) is relatively small and the high pressure within it is reflected back into the pulmonary vessels and right ventricle (RV). The anatomic indicator of this latter physiologic event is severe hypertrophy of the left atrial and right ventricular walls and marked intimal and medial thickening of the pulmonary arteries (PA), arterioles, and veins (PV). In the other extreme, the left atrial cavity is of giant size and its wall is thin. It is thus able to "absorb" the left ventricular (LV) pressure without reflecting it back into the pulmonary vessels or right ventricle. As a consequence, the pulmonary vessels remain normal and the right ventricular wall does not thicken. PT = pulmonary trunk; RA = right atrium. (Reprinted, by permission, from Roberts et al.[47])

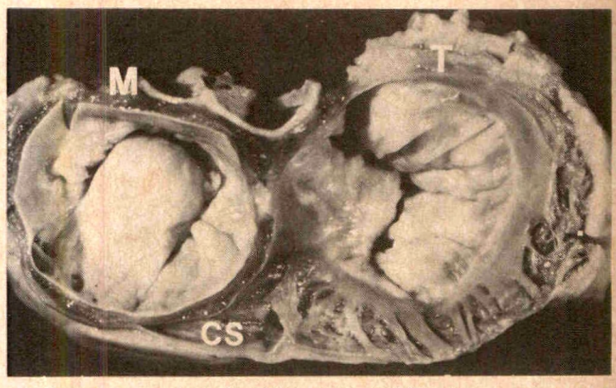

FIGURE 19. Prolapsing mitral (M) and tricuspid (T) valves from the atrial sides in a 55-year-old man (DCMEO #77-05-359) who died suddenly and unexpectedly while at a dance. The patient was known to have had a precordial systolic click and a late systolic murmur since age 36 years but had always been asymptomatic. The M-mode echocardiogram was typical of mitral prolapse. At necropsy, a huge prolapsing "scallop" of the posterior mitral leaflet was present and at least 1 chorda tendinea to this leaflet had ruptured. The leaflet area of the tricuspid valve also was considerably increased. CS = coronary sinus.

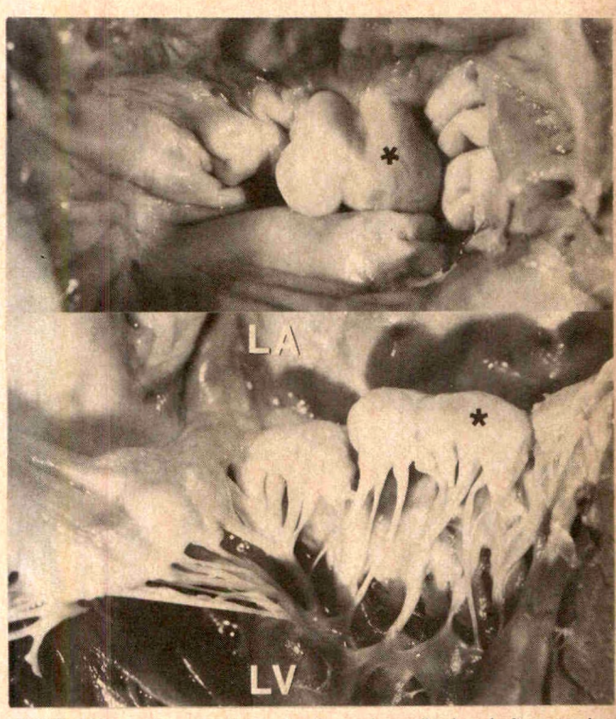

FIGURE 20. Prolapsed mitral valve from above (**top**) and after opening (**bottom**) in an 88-year-old woman who died when hit by an automobile. The patient had had no symptoms of cardiac dysfunction. The **asterisk** indicates the most prolapsed portion of posterior mitral leaflet. echocardiograms; none demonstrated prolapse. Left ventriculograms, performed in all 97 patients, indicated prolapse in only 16 (27%) of the 60 prolapse patients and in none of the other 37 patients with other causes. Selective coronary angiograms were performed in 53 (55%) of the 97 patients. All 29 with MR secondary to coronary heart disease had significant (>50% diameter reduction) coronary narrowing demonstrated angiographically in at least 2 of the 3 major coronary arteries. Of the 60 patients with mitral prolapse, coronary angiograms were

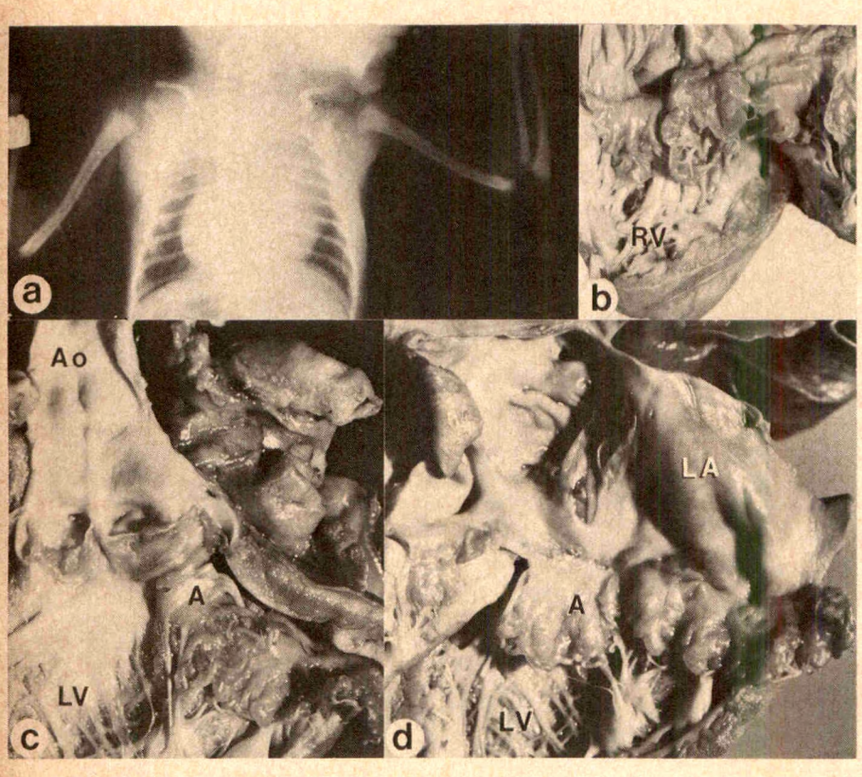

FIGURE 21. Congenital floppy mitral valve and floppy tricuspid valve in a 2-day-old boy (A67-236) who had long toes and fingers, a high-arched palate, and a grade 3/6 precordial systolic murmur typical of mitral regurgitation when examined. The heart was enlarged (**a**) and the infant died of congestive cardiac failure. At necropsy, the intima of the ascending aorta (Ao) was wrinkled (**c**), suggesting that the underlying media was abnormal at this early stage. Shown here are the opened aorta, aortic valve, and left ventricle (LV). A = anterior mitral leaflet. **d,** opened left atrium (LA), mitral valve, and left ventricle (LV). The mitral leaflets are considerably elongated in both longitudinal and transverse dimensions. The left atrium is dilated. **b,** the tricuspid valve leaflets also are elongated in both transverse and longitudinal dimensions. RA = right atrium; RV = right ventricle. FIGURE 22. Posteroanterior chest roentgenogram (**left**) and opened left atrium, mitral valve, and left ventricle (**right**) in a 28-year-old man (A63-25) who had the onset of exertional dyspnea 4 years before death and evidence of overt congestive heart failure for 1 year before death. He never had a murmur of aortic regurgitation. At necropsy, the aorta was normal both grossly and histologically. The mitral valve anulus (**dotted line**) is greatly dilated (17 cm) and the length of the cusps from basal attachment to distal margin is elongated without elongation of the chordae tendineae. The vertebral column is greatly deformed (**left**). (Reprinted, by permission, from Roberts and Honig.[40])

performed in 23; only 3 (13%) had significant coronary narrowing, limited in each to 1 (right) coronary artery. Auscultation and hemodynamic data at cardiac catheterization were not helpful in delineating the origin of the MR. None of the 97 patients—including the 60 classified as having prolapse—had systolic clicks and the systolic precordial murmurs in all 97 patients were holosystolic. The average pulmonary arterial, left atrial (or pulmonary arterial wedge), and left ventricular pressures were similar in the 97 patients irrespective of the origin of the MR. The systolic systemic arterial pressures, however, were significantly higher in the patients with mitral prolapse and ruptured chordae tendineae than in those with mitral prolapse and intact chordae tendineae.

Surprisingly, few reports are available describing the various causes of MR in large numbers of patients. Furthermore, we[12] were unable to find any reports concerning the causes of pure MR in groups of patients in whom any associated MS or aortic valve dysfunction had been excluded by appropriate hemodynamic and angiographic studies. The most frequently cited report describing patients with MR appears to be that by Selzer and Katayama,[62] who summarized findings in

230 patients. Although 212 of their 230 patients had pure MR defined as the "absence of a late diastolic gradient across the valve . . . except in tachycardia" at the time of cardiac catheterization, some of their patients had MS at other times. Of their 230 patients, 88 were classified as having MR of rheumatic origin, and I suspect that nearly half (42 patients) had MS at some time in their course: 5 had had mitral commissurotomies for MS and severe MR developed subsequently; 8 of their rheumatic patients had MR only after the development of infective endocarditis, and it is probable that 1 or more previously had had MS; and 33 (38%) of their 88 rheumatic patients had sizeable calcific deposits in their mitral valves, a finding quite unusual in patients without some degree of MS. (Only 4 of our 97 patients had grossly visible calcific deposits in their excised mitral valves.) It is also difficult to compare the observations in our patients with those reported by Selzer and Katayama because of differences in patient selection. We[12] studied only patients who were in functional classes III and IV (New York Heart Association) because of congestive heart failure; all underwent mitral valve replacement and all had their valves examined by the same observer. Seventy (30%) of the 230 patients reported by Selzer and Katayama were in functional classes I or II, and mitral valve operations were performed in just over half of the 230 patients. Additionally, they included children, which we did not. Finally, we excluded patients with any aortic valve dysfunction, which may or may not have been the case in the study by Selzer and Katayama.

In the past, rheumatic heart disease has been considered the most common cause of severe MR, but it is likely that most or many patients so classified in older studies had some degree of MS. Because there has been such a strong tendency in the past to believe that severe MR was usually the result of rheumatic heart disease, other causes commonly have not been sought and definitions of "rheumatic" MR have not been precisely stated. Before 1963, most prolapsing or floppy mitral valves almost certainly were called "rheumatic" in origin at necropsy or operation. Our report[12] morphologically defined a prolapsed mitral valve which can cause severe MR; its anular circumference and leaflet area are clearly increased over that of other valves causing MR, except when the chordae tendineae of the prolapsing valve are ruptured. It is hoped that this definition will prevent indiscriminate labeling of mitral disease in the future as rheumatic when other evidences of previous rheumatic carditis are lacking.

Congenital MR is usually associated with other anomalities.[2,6,30–40] "*Isolated*" congenital MR is usually accompanied by *endocardial fibroelastosis of the left ventricle.* It is sometimes difficult, however, to determine what causes the mitral valve to be regurgitant in this circumstance. Neither is it always clear why the mitral valve is frequently regurgitant in patients with *partial atrioventricular canal* (endocardial cushion defect).[30,31,37] Nearly all patients with partial atrioventricular canal have a cleft, either partial or complete, in the anterior mitral leaflet. It would be easy to attribute the MR to the cleft, but the MR usually disap-

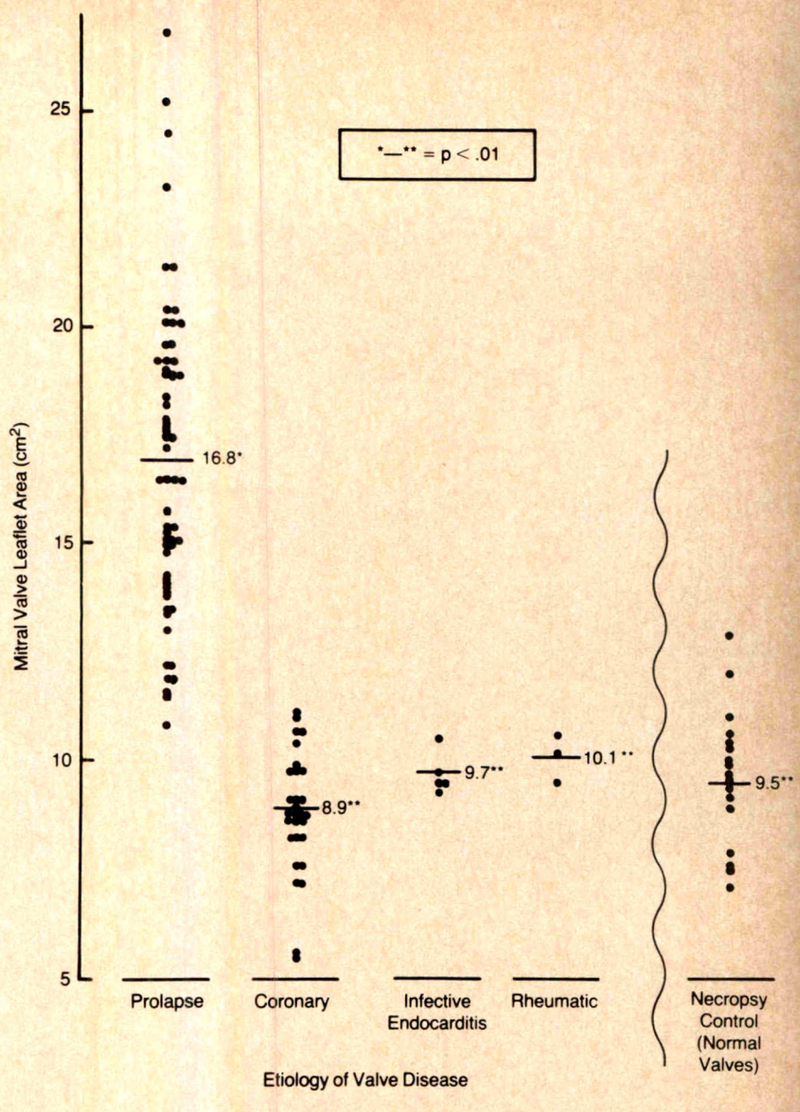

FIGURE 26. Graph showing mitral valve leaflet area (in centimeters squared) in each of the 97 patients with operatively excised mitral valves in the 4 conditions causing chronic, isolated, pure mitral regurgitation and in 18 necropsy control valves. (Reprinted, by permission, from Waller et al.[12])

pears after operative closure of the associated defect in the lowermost portion of the atrial septum (ostium primum defect), irrespective of whether the cleft in the anterior mitral leaflet is closed by suture. For the same reason, it is unlikely that the anomalous chordae tendineae that insert onto the crest of the ventricular septum play a significant role in the production of MR. It is helpful to think of partial atrioventricular canal as a syndrome consisting of 5 components: (1) defect in the lowermost portion of atrial septum; (2) cleft in the anterior mitral leaflet; (3) absence of tissue, either partial or complete, in the septal tricuspid valve leaflet; (4) anomalous chordae tendineae from the anterior mitral leaflet to the crest of ventricular septum; and (5) ventricular septal defect. The syndrome may include all 5 components or may have as few as 2; most commonly, the first 4 components are present. A cleft in the anterior mitral leaflet may occur, however, in the absence of a defect in the lowermost portion of the atrial septum.[63] These individuals usually present with evidence of isolated MR or with features of isolated ventricular septal defect. Of 21 necropsy patients with a cleft in the anterior mitral leaflet unassociated with a defect in the lowermost portion of the atrial septum reported by Segni and Edwards,[63] 11 had no defect in any portion of the atrial or ventricular septa and the other 9 had associated defects, usually ventricular septal defect or a fossa ovale type atrial septal defect or both. Occasionally, the ostium primum defect may be so small that the shunt through it is missed or is only trivial; these patients also may present with essentially pure MR.[30,31]

Corrected transposition is an entity that has produced much confusion. Corrected transposition and complete transposition are quite different; the only thing they have in common is the word "transposition." Complete transposition is essentially 1 defect: the great arteries are transposed, so that the aorta arises from the right ventricle and the pulmonary trunk from the left ventricle. In corrected transposition, the great arteries

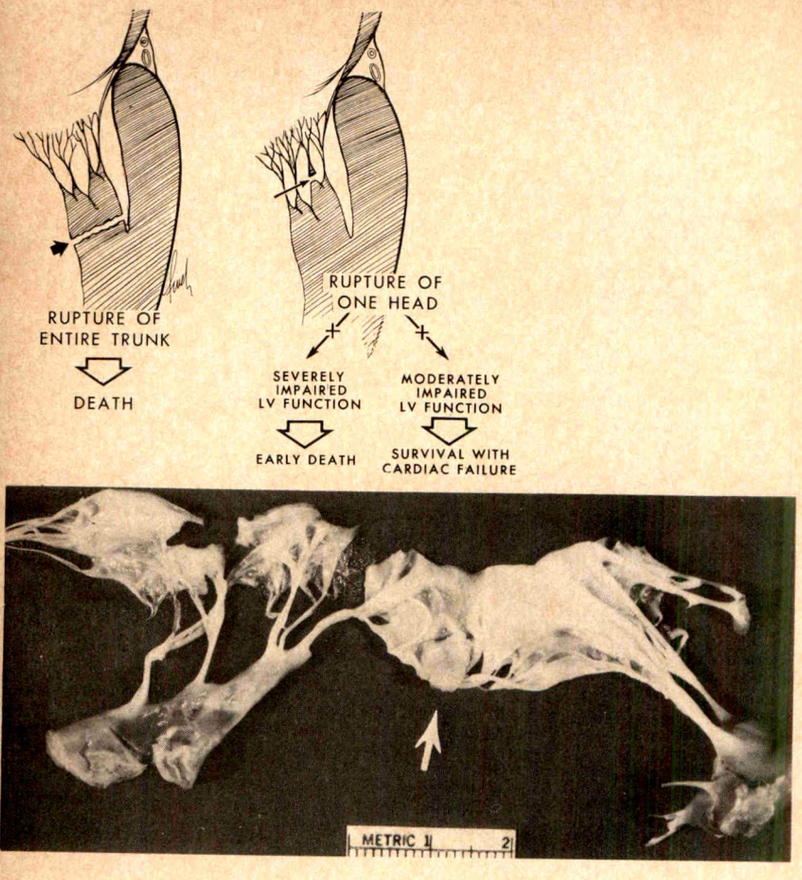

FIGURE 27. Top, diagram of the types of, and possible consequences of, papillary muscle rupture during acute myocardial infarction. It is likely that rupture of the entire trunk (**left**) is incompatible with survival in any patient since a major portion of the support to both valve leaflets is destroyed. With rupture of an apical head (**right**), survival would appear to depend on the extent to which the function of the left ventricle has been impaired by the infarct. With severely impaired ventricular function, the additional burden of even modest mitral regurgitation may be intolerable, and death will ensue. If the left ventricle is less severely compromised, survival is possible for weeks or months, but congestive cardiac failure will almost invariably develop. **Bottom,** rupture of a portion of 1 papillary muscle during acute myocardial infarction in a 51-year-old man (S67-813) who underwent mitral valve replacement 3 months after the onset of the infarction. Preoperatively, the pulmonary arterial pressure was 60/28 mm Hg; pulmonary arterial wedge pressure, mean 28, v42; left ventricular pressure 74/17 mm Hg; and cardiac index, 1.7 liters/min/m^2. The leaflets are normal but the posteromedial papillary muscle is necrotic and fibrotic and a portion of it (**arrow**) is entwined in chordae tendineae at the margin of the anterior mitral leaflet. This is a view of the ventricular aspects of the leaflets. LV = left ventricular. (Reprinted, by permission, from Roberts and Perloff.[2])

also are transposed, but, in addition, the ventricles, atrioventricular valves, coronary arteries, and conduction system are inverted. Patients with complete transposition die because they have inadequate communications between the 2 circuits. Patients with corrected transposition theoretically should be able to live a full lifespan, but usually this is not the case because associated defects—namely, ventricular septal defect or regurgitation of the left-sided atrioventricular valve, or both—cause the heart to function abnormally. Abnormalities of the left-sided atrioventricular valve, a systemic valve but anatomically a tricuspid valve, are the most common associated anomalies in corrected transposition.[64] Of the anomalies, the most frequent is the Ebstein-type malformation. These valves are intrinsically regurgitant because the chordae are short and the leaflets are closely adherent to the ventricular endocardium.

A mitral valve may be abnormal anatomically and yet function entirely normally. A congenital malformation illustrating this point is the *double-orifice mitral valve*, which looks like a double-barreled shotgun.[65] Generally, both orifices are totally competent and the patient should be asymptomatic.

Papillary Muscle Dysfunction

Rupture of a portion of a papillary muscle was not appreciated until 15 years ago.[48] The original concept of papillary muscle rupture was rupture of its entire trunk, caused either by myocardial infarction from coronary narrowing or by trauma (Fig. 27). Complete transsection of a left ventricular papillary muscle is incompatible with life because about 60 chordae tendineae are thus disrupted. More frequent is rupture of a portion of a papillary muscle. In this situation, the largest amount of MR is probably caused by the rupture, but all these patients have severe necrosis of the remaining portion of the papillary muscle and the latter probably contributes to the regurgitation. When 1 head of a papillary muscle is ruptured, about 10 third-order chordae tendineae are disrupted.

Necrosis or fibrosis of a papillary muscle without rupture is far more common than rupture. Table II lists conditions frequently associated with papillary muscle dysfunction, particularly necrosis or fibrosis.[3] Although coronary arterial luminal narrowing is the most frequent cause of papillary muscle necrosis or fibrosis, many other conditions may be accompanied by papillary muscle lesions. The papillary muscles are fibrotic or necrotic in so many conditions because they are the last structures in the heart to be perfused by arterial blood. Of the 2 left ventricular papillary muscles, the posteromedial one has the poorer blood supply, and, consequently, lesions are more frequent in it than in the anterolateral muscle. The posteromedial muscle receives its oxygen mainly from blood passing through the right coronary artery. The mouth of this artery may be >15 cm from the apex of the posteromedial muscle. To perfuse it, blood must pass through the entire thickness of left ventricular wall, turn uphill (so to speak), and

ascend a distance equivalent to 2 more full thicknesses of left ventricular wall. Thus, the apices of the papillary muscles are the sites farthest from the coronary ostia, and they receive oxygen only after the other myocardium has had an opportunity to extract its oxygen needs. Although the surfaces of the papillary muscles are entirely bathed by intracavitary ventricular blood, only a small amount of oxygen diffuses into these structures from the intracavitary blood.

The most common cause of papillary muscle necrosis or fibrosis is *narrowing of the coronary arterial lumen by atherosclerotic plaques.* The posteromedial papillary muscle is usually involved in acute posterior myocardial infarction. In anterior wall infarction, however, the anterolateral papillary muscle may be spared, presumably because its blood supply is better than that of the posteromedial muscle. Since infarction limited to the ventricular septum or to the lateral portion of the left ventricular free wall (that is, the portions of the left ventricular wall unassociated with papillary muscles) is rare, the papillary muscles are usually involved when myocardial infarction occurs. It is, therefore, surprising that papillary muscle dysfunction is not more frequent during or after acute myocardial infarction.

In patients with *left ventricular outflow obstruction*, lesions often occur in the papillary muscles. Valvular aortic stenosis, whether in infants or in adults, when superimposed on a congenitally malformed valve, either unicuspid or bicuspid, is nearly always associated with fibrosis and atrophy of at least the posteromedial papillary muscle. Rheumatic valvular aortic stenosis combined with organic MS or MR, however, infrequently is associated with papillary muscle fibrosis or atrophy. Nearly all adult patients with discrete subaortic stenosis or hypertrophic cardiomyopathy with or without diffuse subaortic stenosis have small fibrous scars in both left ventricular papillary muscles, but atrophy of 1 or both muscles is uncommon.[39]

Foci of necrosis also are common in patients with fatal *severe valvular regurgitation of recent onset.* Among 47 patients dying of active valvular infective endocarditis and examined personally, 34 (72%) had necrotic lesions in 1 or both left ventricular papillary muscles; none had significant narrowing of the extramural coronary arteries. Most patients had pure aortic regurgitation, but some had pure MR secondary to the active infective endocarditis. Severely diminished cardiac output resulting in poor myocardial perfusion was believed the cause of the papillary muscle necrosis in these patients.

Small fibrous scars in the papillary muscles are common in patients with *systemic hypertension*, but atrophy of these muscles is infrequent in this condition, unless coronary heart disease also is present. In left ventricular hypertrophy of any cause, the hypertrophy of the papillary muscles should probably be proportional to that of the left ventricular free wall or ventricular septum. This proportional hypertrophy usually exists in patients with systemic hypertension but is infrequent in patients with left ventricular outflow obstruction.

Fibrosis with atrophy of the papillary muscles is to be expected in patients with primary *endocardial fibroelastosis* of the left ventricle. Histologically, the thickened endocardium in this condition is similar to the media of the aorta, being characterized by elastic fibrils running parallel to one another and to the surface. Primary left ventricular endocardial fibroelastosis may be an anatomic expression of chronically inadequate coronary arterial perfusion of the left ventricle; since the posteromedial papillary muscle is the least well-perfused portion of the heart, this structure is affected the most. In the congenital anomaly, origin of the left or both coronary arteries from the pulmonary trunk, diffuse endocardial fibroelastosis of the left ventricle is nearly always an associated lesion.[33] Fibrosis and atrophy of the left ventricular papillary muscles are to be expected in this anomaly, and these patients may present clinically with features of pure MR.

Foci of fibrosis or necrosis in the left ventricular papillary muscles are infrequent in patients with dilated cardiomyopathy.[54,66] Rarely, *myocarditis* may be localized to papillary muscle and adjacent left ventricular free wall.[67] Patients with the *neurogenic heart diseases* (Friedreich's ataxia, progressive muscular dystrophy, and myotonic muscular dystrophy) generally have scarred left ventricular papillary muscles, especially the posteromedial ones.[68] The African cardiomyopathy, *endomyocardial fibrosis*, may be associated with extensive scarring of the papillary muscles.[54] In this condition the posteromedial muscle is usually covered by a thrombus or by dense fibrous tissue that probably represents organized thrombus. Likewise, *Löffler's fibroplastic parietal endocarditis*, which may be 1 stage of endomyocardial fibrosis,[53] is usually associated with extensive scarring of 1 or both papillary muscles.

The papillary muscles are subject to various infiltrative processes, just like any other portion of myo-

TABLE II Spectrum of Left Ventricular Papillary Muscle Dysfunction

I. Rupture of papillary muscle
  A. Total ("belly" or trunk)
    1. Rapid death
    2. Survival—not described
  B. Partial ("head")
    1. Rapid death
    2. Survival but chronic congestive cardiac failure
II. Fibrosis or necrosis of papillary muscle without rupture
  A. With coronary arterial narrowing
    1. Acute myocardial infarct
    2. Healed myocardial infarct
  B. Without coronary arterial narrowing
    1. Acute
    2. Chronic
      a. Valvular, subvalvular (discrete and diffuse) and supravalvular aortic stenosis
      b. Systemic hypertension
      c. Origin of left coronary artery from pulmonary trunk
      d. Primary endocardial fibroelastosis
      e. Endomyocardial fibrosis
      f. Löffler's fibroplastic parietal endocarditis
      g. Diffuse (primary) myocardial disease
      h. Focal myocardial disease
        1. Idiopathic
        2. "Neurogenic" heart disease
        3. Infectious
III. Normal or near-normal papillary muscles but severe fibrosis or necrosis in adjacent left ventricular free wall with and without coronary arterial narrowing

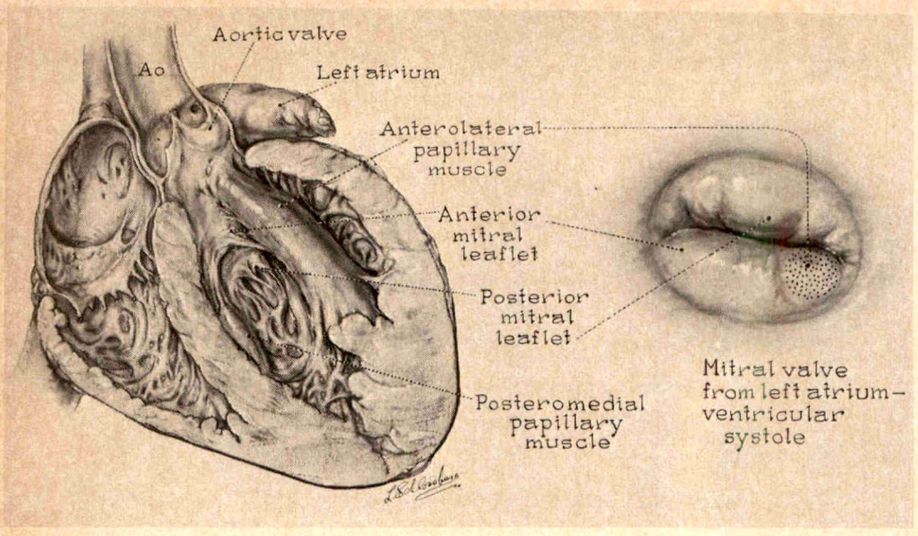

FIGURE 28. Drawing of heart in a 23-year-old man (DCMEO #80-02-134) who died from idiopathic dilated cardiomyopathy. An incidental finding at necropsy was the insertion of the anterolateral papillary muscle directly onto the anterior mitral leaflet. This congenital anomaly has been observed personally in about 5 cases at necropsy. It appears to have no functional significance. Ao = aorta.

cardium. *Pyogenic abscesses*, *Aschoff bodies*, *granulomas*,[67] *neoplasms*,[69–71] *amyloid*,[72] *iron*,[73] *and air*[74] have all been observed in these structures. Congestive heart failure from severe MR may be the initial symptom of cardiac *sarcoidosis*.[67]

The most frequent congenital malformation of papillary muscles is the occurrence of only 1 such muscle in the left ventricle. In this condition, described as the *parachute mitral valve*, all mitral chordae tendineae are attached to the 1 left ventricular papillary muscle (Fig. 11). The resulting mitral valve is usually stenotic, but it may be purely regurgitant or it may function normally.[35] The single papillary muscle is usually associated with other malformations, including a supramitral valve ring, diffuse subaortic stenosis, and coarctation of the aorta. Other malformations, including valvular aortic stenosis, ventricular septal defect, and valvular pulmonic stenosis, also may occur.

There may be not only 1 too few papillary muscles but also 1 too many. An *accessory papillary muscle* is usually of no functional significance, but it has been seen in association with congenital MR. When 2 papillary muscles are present, 1 or both may still be congenitally malformed. One or both papillary muscles may be abnormally large and malpositioned with attachment onto the anterior mitral leaflet, creating the potential at least for valvular stenosis or regurgitation (Fig. 28). Both papillary muscles also may be poorly developed and small. This finding is particularly characteristic with origin of the left coronary artery or both coronary arteries from the pulmonary trunk. In this situation, the papillary muscles arise more cephalad than normal from the left ventricular free wall.

Both left ventricular papillary muscles usually are excised either completely or incompletely at operations to replace the mitral valve. The myocardium of the free wall at the sites of excision of these muscles is always infiltrated by inflammatory cells when this area is examined in the early postoperative period. With time, these areas are covered by dense fibroelastic tissue simulating the composition of the media of the aorta. If the papillary muscles are not excised when the mitral leaflets and chordae tendineae are excised during mitral valve replacement, the papillary muscles atrophy and are focally replaced by fibrous tissue; the myocardial cells become disorganized.[75] When the papillary muscles are excised at operation, each is grasped by a clamp extending through the mitral orifice from the left atrium. If the papillary muscles are pulled too vigorously by the clamp during their excision, portions of left ventricular free wall also may be excised. The result may be perforation or severe thinning of the left ventricular wall. The latter may lead to the formation of a functioning or anatomic aneurysm or both.[76,77]

Mitral Anulus

Although it may accompany left ventricular dilation, mitral anular dilation, except in patients with prolapsing or floppy mitral valves,[12] is a rare cause of MR[59]; in the past, most patients with MR that was believed the result of mitral anular dilation probably had papillary muscle dysfunction. Mitral anular dilation to a degree capable of causing MR probably does not occur except in association with mitral valve prolapse because the surface area of the mitral leaflets is more than twice the area of the mitral orifice, and the anulus contracts during ventricular systole.[2] The mitral ring has a sphincter-like action because the mitral orifice is smaller during ventricular systole than during diastole. In patients with dilated left ventricles, the widest diameter does not occur at the left ventricular base, the area that includes the mitral anulus, but in the midportion of the chamber between apex and base (Fig. 29). In fact, the base of the left ventricle is prevented from dilating freely because the "fibrous skeleton" is attached to it, whereas the midportion of the left ventricle is not so restricted. Indeed, severe left ventricular dilation may occur without any dilation of the mitral anulus.

Although it is now well known that MR may occur in patients with dilated left ventricles from any cause

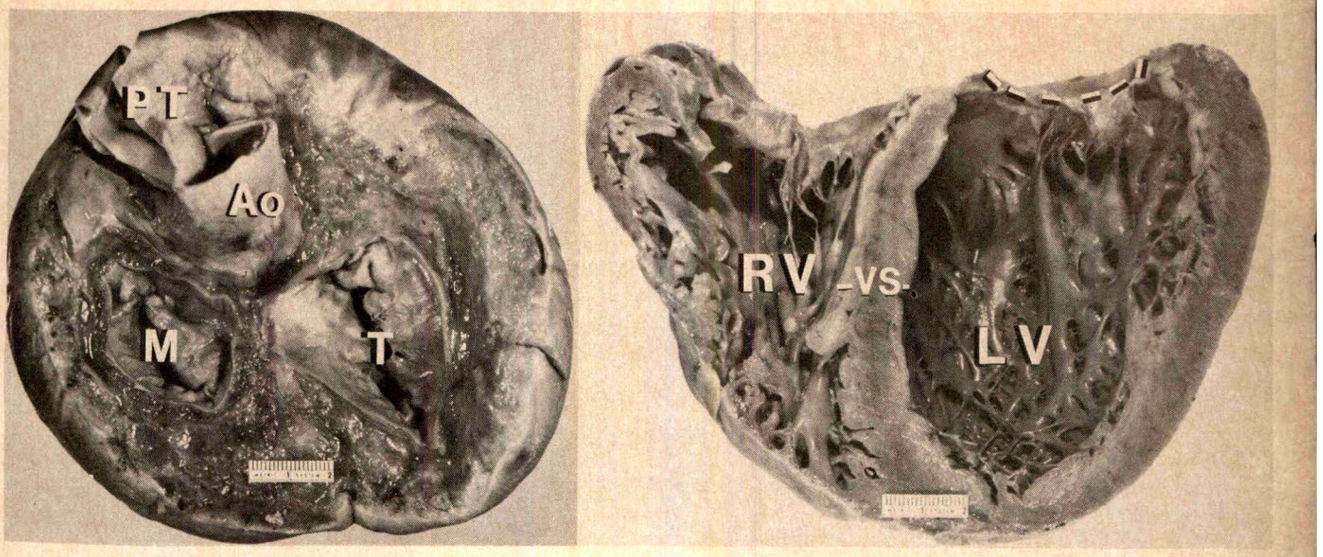

FIGURE 29. The heart of a 34-year-old man (DCGH #74A-65) with idiopathic dilated cardiomyopathy and clinical evidence of both tricuspid and mitral regurgitation of severe degree. Both ventricles are considerably dilated. The greatest increase in dimension of the right (RV) is in the area of the tricuspid valve anulus. The tricuspid valve orifice (T) admitted 4 fingers readily, indicating its proximal diameter to be about 8 cm. In contrast, the maximal diameter of the left ventricle (LV) was about midway between the apex and the mitral anulus. The mitral orifice (M) only admitted 2 fingers, indicating that its maximal diameter was about 4 cm. The mitral regurgitation resulted, therefore, not from anular dilatation, which was mild, but probably from altered angulation of the left ventricular papillary muscles. Ao = aorta.

without associated left ventricular necrosis or fibrosis, it is less well recognized that necrosis or fibrosis of the left ventricular free wall, unassociated with left ventricular dilation or papillary muscle or mitral tissue lesions, also may be associated with MR. Generally, the scarring or necrosis of the myocardium adjacent to the papillary muscles fails to move or moves paradoxically during ventricular systole, and the abnormal ventricular contraction may lead to abnormal papillary muscle anchoring, resulting in MR. Anatomic left ventricular aneurysms unassociated with papillary muscle necrosis or fibrosis may cause MR by the same mechanism.

Abnormal pulling on the papillary muscles unassociated with left ventricular necrosis or fibrosis or cavity

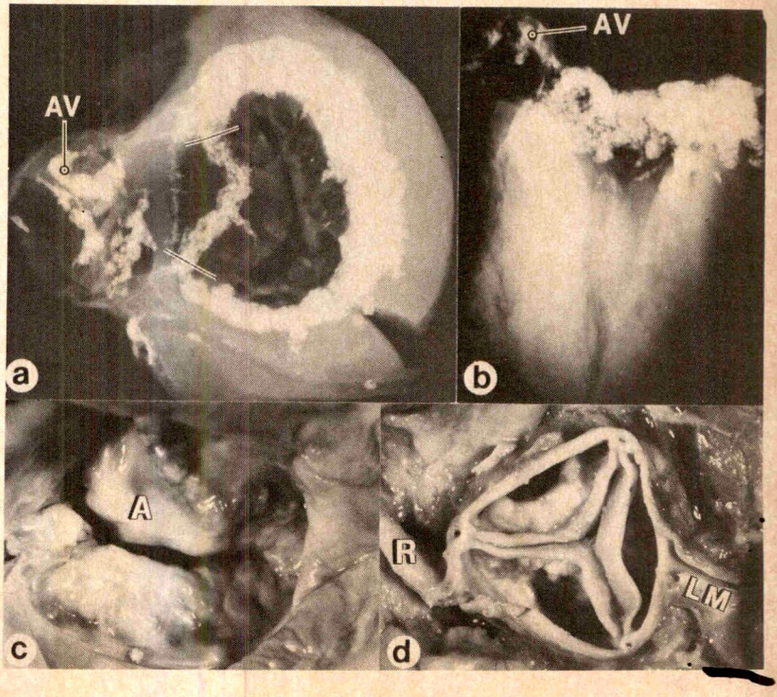

FIGURE 30. Massive calcific deposits in the mitral anulus (**a, b,** and **c**), aortic valve (AV) (**a, b,** and **d**), and coronary arteries (**a** and **b**) in an 82-year-old man (NNMC #A70-200) who had Paget's disease of bone. The short bar of calcium between the lines in **a** is that extending across the anterior (A) mitral leaflet. The radiogram in **a** is a cephalad-caudal orientation, and that in **b,** a lateral view. The mitral valve as observed from the left atrium is shown in **c,** and the aortic valve from the aorta in **d.** LM and R = left main and right coronary arteries. (Reprinted, by permission, from Roberts and Waller.[79])

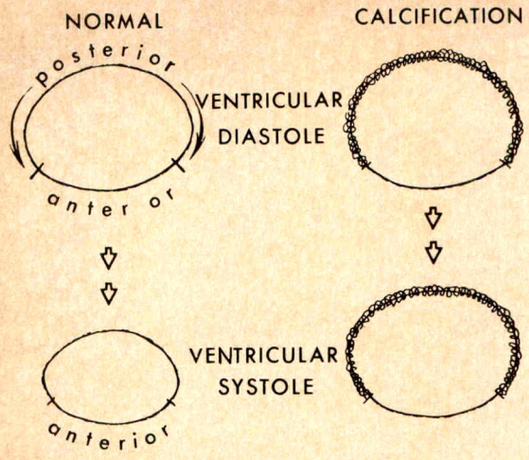

FIGURE 31. Mechanism of mitral regurgitation in patients with calcification of the mitral anulus. During ventricular systole, the base of the left ventricle contracts like a sphincter. Included in the base of the left ventricle is the anulus behind the posterior mitral leaflet. Thus, this circumference decreases during systole. If, however, the anulus behind the posterior mitral leaflet is calcified, the sphincter-like contraction of the left ventricular base may be prevented from occurring. The area of the mitral orifice thus is not decreased, and mild degrees of mitral regurgitation may result. (Reprinted, by permission, from Roberts and Perloff.[2])

dilation may occur in patients with *hypertrophic cardiomyopathy*; this mechanism may account for their MR.[51,54] The huge thickening of the ventricular septum may distort or bend the anterolateral papillary muscle and prevent proper contraction of this structure during ventricular systole. In addition to actual bending of the anterolateral left ventricular papillary muscle, however, the mitral leaflets in adults with hypertrophic cardiomyopathy are always thickened. The thickening of the anterior mitral leaflet appears to be the result of its contact with the mural endocardium in the left ventricular outflow tract during ventricular systole. But the posterior mitral leaflet also is thickened, probably a result of its contacting itself abnormally during ventricular systole. The mitral leaflets and chordae tendineae are within the left ventricular cavity, which in hypertrophic cardiomyopathy is relatively small; as a consequence, space within the left ventricle may be inadequate to easily accommodate the mitral leaflets and chordae, and with vigorous contractions portions of the posterior leaflet contact other portions of the same leaflet abnormally. Fibrous thickening is the consequence. The MR in hypertrophic cardiomyopathy usually disappears after operative excision or incision of myocardium in the left ventricular outflow tract.[51]

Calcification of the mitral anulus is one of the more frequent abnormalities of the heart. Mitral anular calcification is generally considered to be a disease of elderly women. Indeed, of 14 patients with "massive" mitral anular calcification reported by Korn et al[78] 21 years ago, all were women and all were over 65 years of age. It is incorrect, however, to believe that this entity is reserved for a particular sex at a particular time in life. During the past 14 years I have examined over 300 patients with mitral anular calcium at necropsy. Of the first 200 analyzed systematically, 47% were men and 53% were women. Of the 200 patients, 141 (70%) were over age 65 years and 17 (8%) were aged 45 years or less. The extent of the mitral anular calcium was graded 1^+ to 4^+: in 110 patients (55%) the deposits were graded 1^+ or 2^+ and in 90 patients (45%) grade 3^+ or 4^+. The calcium in 198 patients was limited to the anular region behind posterior mitral leaflet, usually forming a C-shaped configuration; in 2 patients, the calcium extended across the anterior mitral leaflet to form an O-shaped configuration[79] (Fig. 30). Of the 38 patients with 4^+ deposits, 76% were women. Thus, although mitral anular calcium of any degree appears to occur with similar frequency in men and women, the larger deposits (those likely to be seen on the chest roentgenogram) are more frequent in women. Calcium deposits also were present on the aortic aspects of the aortic valve cusps in 138 (69%) of the 200 patients (64 [32%] of whom had aortic valve stenosis) and in the coronary arteries in 168 (84%) patients.

Factors predisposing to mitral anular calcium were found in 80% of the 200 patients. These included elevation (>140 mm Hg) of left ventricular systolic pressure (142 patients), diabetes mellitus (39 patients), chronic hypercalcemia (9 patients),[80] prolapsing mitral valve (6 patients), the Marfan syndrome (5 patients),[40] left-to-right shunt (secundum type atrial septal defect) (3 patients), and the Hurler syndrome (2 patients).[46] Mitral anular calcium also may form late at sites of attachment of prosthetic mitral valves.[81]

The association of mitral anular calcium with calcific deposits in the coronary arteries and aortic valve cusps, the lack of mitral anular deposits in persons living in environments where the total serum cholesterol is ≤150 mg/dl, and the frequent occurrence of factors predisposing to atherosclerosis in patients with mitral anular calcium supports a common etiologic basis for both mitral anular calcium and atherosclerosis.

The functional consequences of mitral anular calcium are 2, namely MR or MS, and rarely, if ever, both. The presence of either MR or MS is a function of the amount of anular calcium present and also probably the size of the left ventricular cavity. The most common functional consequence, of course, is MR, which is nearly always of only mild degree and never of severe degree except in a patient with associated mitral anular dilatation in the setting of mitral valve prolapse.[12] The frequency of a murmur typical of MR is nearly always present in patients with $4^+/4^+$ anular deposits and is rarely the consequence of anular deposits if the extent of the latter is only $1^+/4^+$. The mechanism of MR in patients with mitral anular calcium is depicted graphically in Figure 31. Mitral stenosis as a consequence of mitral anular calcium has been observed only in the presence of huge ($4^+/4^+$) mitral anular deposits associated with severe left ventricular hypertrophy without dilatation, usually the consequence of associated left ventricular outflow obstruction.[25]

Improved Cross-Sectional Echocardiographic Technique For Visualization of the Retrocardiac Descending Aorta In Its Long Axis

Normal Findings and Abnormalities in Saccular And/or Dissecting Aneurysms

PATRICIA C. COME, MD

The feasibility of using an improved ultrasonic technique for visualization of the retrocardiac descending thoracic aorta was studied in 50 consecutive patients. Both anterior and posterior aortic walls were well delineated in long as well as short axis in 92%. The mean length of the visualized portion of the retrocardiac aorta was 8.4 cm (range 4.5 to 13) and exceeded 6 cm in 40 of 46 patients. The mean diameter was 2.0 cm (range 1.3 to 2.7).

Five patients with saccular (1 patient) and/or dissecting (all 5 patients) aneurysms involving the retrocardiac aorta were also examined. Abnormalities essentially identical to those seen with computerized tomography and aortography were noted. Intimal flaps were visualized by ultrasound in all 5 patients and were seen to oscillate reproducibly with the cardiac cycle, suggesting differential rates of filling of false and true lumens.

This and other previous cross-sectional echocardiographic studies of the ascending aorta suggest that ultrasound may be useful in the initial evaluation of patients presenting with symptoms or signs suggestive of acute or chronic aortic disease.

Cross-sectional echocardiography has permitted recognition of a variety of aortic abnormalities, including supravalvular aortic stenosis, aortic aneurysms, and coarctation.[1–8] While recognition of the retrocardiac portion of the descending aorta has been described,[5–7,9] diagnosis of abnormalities in that region has been considered more difficult than recognition of aortic root disease.

This prospective study was designed to assess the usefulness of a new echocardiographic technique in defining the retrocardiac descending aorta in its long and short axes. It reports the echocardiographic findings in 50 consecutive patients. In addition, the echocardiographic features of 5 patients with retrocardiac expanding or dissecting aortic aneurysms, or both, are described.

Methods

Fifty consecutive patients, without apparent aortic disease, were studied in the supine and 30° left lateral positions using a Hoffrel 201A/514 mechanical sector scanner. With the transducer in the third or fourth intercostal space just to the left of the sternum, the descending thoracic aorta was identified in its short axis as a circular structure posterior to the left atrium, to the atrioventricular groove, or to the left ventricle. The transducer was then rotated, generally approximately 90°, in an effort to visualize the descending aorta in its long axis. If optimal longitudinal visualization of the aorta was not obtained, the transducer was then moved laterally, and repeated attempts were made to visualize the descending aorta in its short and, subsequently, long axis. The identification of the descending aorta has been verified in our laboratory by injection of saline solution microbubbles into the aorta at the time of cardiac catheterization.

Results

The 50 consecutive patients had a mean age of 56 years (range 15 to 92) and included 25 females and 25 males. Both the anterior and the posterior walls of the retrocardiac descending thoracic aorta were cl[illegible]

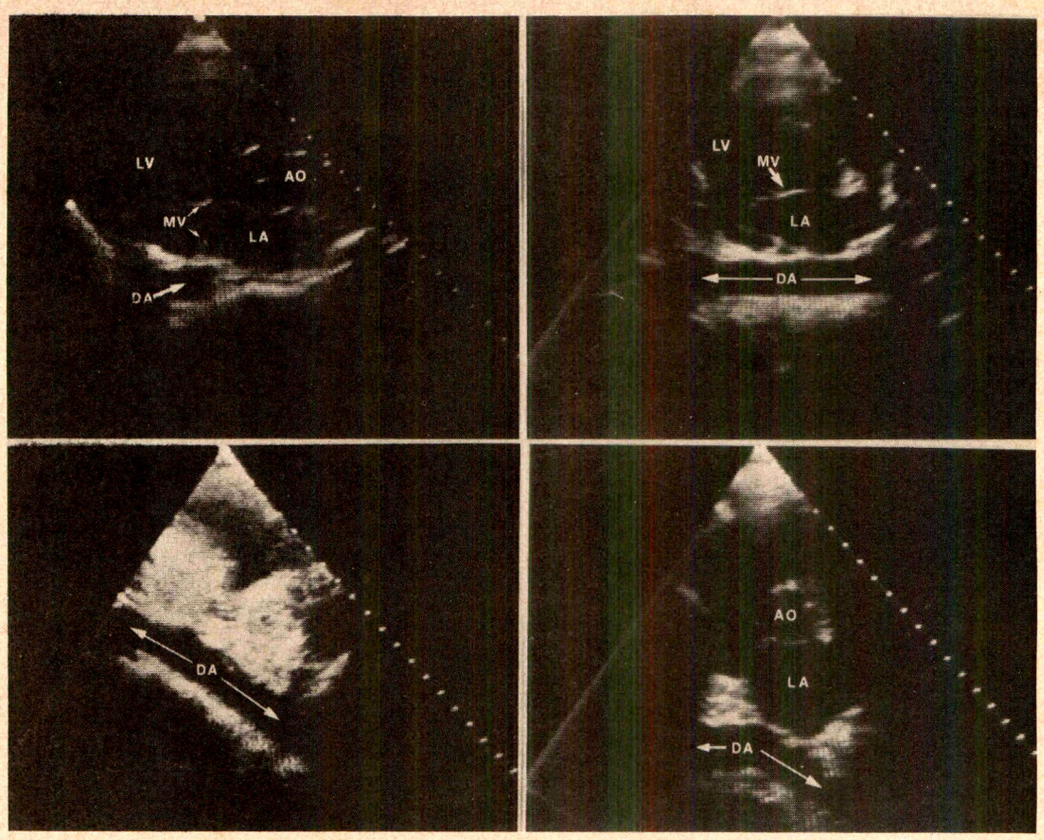

FIGURE 1. Representative cross-sectional echocardiograms obtained in a consecutive series of patients without signs or symptoms of dissection. The technique of visualizing the descending thoracic aorta (DA) is illustrated in the **upper panels.** The DA is first identified in its short axis (**top left**) as a relatively circular structure lying posterior to the junction of the left atrium (LA) and left ventricle (LV). The simultaneously obtained long-axis view of the heart is suboptimal since the transducer was placed several centimeters to the left of the sternum. The DA in its long axis is then obtained by rotation of the transducer approximately 90° from the position of short-axis study (**top right**). The aortic walls are seen to be smooth in this study obtained from a 15-year-old boy. In another patient, aged 88 years, the aortic walls are seen to be less smooth (**bottom left**), suggesting wall irregularities which might potentially arise from atherosclerotic placques. While the DA is generally seen to be a relatively straight, tubular structure, it was observed to be curved in its course in 1 patient, an 83-year-old woman with left atrial enlargement due to rheumatic mitral valve disease (**bottom right**). The left atrial enlargement was likely responsible for the deviation of the course of the DA in this patient. One centimeter markings are displayed on the right side of the sector. AO = aorta; MV = mitral valve.

visualized in long and short axis in 46 (92%). Optimal visualization always required transducer placement at least several centimeters to the left of the sternum, generally at the midclavicular line, and occasionally as far left as the anterior axillary line. In 1 other patient, a longitudinal structure thought to represent the aorta was visualized, but clear transition from the short- to long-axis views of the aorta could not be obtained by rotation of the transducer. The mean length of the aorta visualized was 8.4 cm (range 4.5 to 13) and exceeded 6 cm in 40 patients. Diameter ranged from 1.3 to 2.7 cm (mean 2.0). In its long axis, the aorta generally was a straight tubular structure with parallel walls (Fig. 1). In 1 patient with left atrial enlargement, however, the aorta curved around an enlarged left atrium (Fig. 1). While the anterior and posterior aortic walls generally appeared smooth in young patients, shagginess was often apparent in elderly individuals (Fig. 1). In none of the consecutive patients was there a stationary or oscillating linear echo suspicious for an intimal flap or change in aortic diameter suggestive of a saccular aneurysm.

Patients with aortic aneurysms involving the descending aorta: Five patients with saccular or dissecting aneurysms, or both, involving the retrocardiac descending aorta underwent ultrasound examination. Their clinical features, echocardiographic findings, and abnormalities documented by computerized tomography or aortography are shown in Table I. Figures 2 and 3 illustrate the representative 2-dimensional and M-mode echocardiographic findings. The echocardiographic studies and diagnosis of aortic disease preceded angiographic and tomographic confirmation in 4 patients and followed aortography in the fifth. In each of the 5 cases, the results of ultrasound evaluation were identical to those obtained by aortography or computerized tomography and permitted accurate classification of the aortic dissections into DeBakey types 1 or 3.

Discussion

The development of cross-sectional echocardiography has increased ultrasonic recognition of pathologic abnormalities of the thoracic aorta. The technique described here, and illustrated in 1 patient in a previous

report,[6] was developed to permit optimal visualization of the retrocardiac descending thoracic aorta in its long axis. While the descending aorta in its short axis can usually be visualized behind the left ventricle, the left atrium, or the atrioventricular groove with the transducer placed in the usual position for a long-axis study of the heart, this position rarely permits optimal examination of the retrocardiac aorta in its long axis and may explain the difficulty experienced by others in identifying pathology of the retrocardiac aorta. Movement of the transducer a number of centimeters to the left of the sternum in the third to fifth intercostal space, occasionally as far laterally as the midclavicular or anterior axillary lines, will, however, permit good visualization of this part of the aorta in the vast majority of patients. In each of our patients with descending aortic pathology, such a transducer position permitted recognition of a dissecting or expanding aortic aneurysm, or both. In this position, the heart serves as a window through which the ultrasound beam can be passed to visualize the lower portion of the descending thoracic aorta. Since lung is not present between the chest wall and the aorta at this level, it is not surprising that the aorta can easily be visualized in most patients. Improved visualization with the more leftward transducer position likely reflects the fact that the aorta descends within the left chest. The ability, using this transducer position, to visualize the aorta changing from its short to long axis during 90° rotation of the transducer will also permit differentiation of the aorta from other structures, such as the coronary sinus, which may also be visualized in short axis posterior to the cardiac chambers.

Use of the modified left parasternal technique appears sensitive in identifying abnormalities of the de-

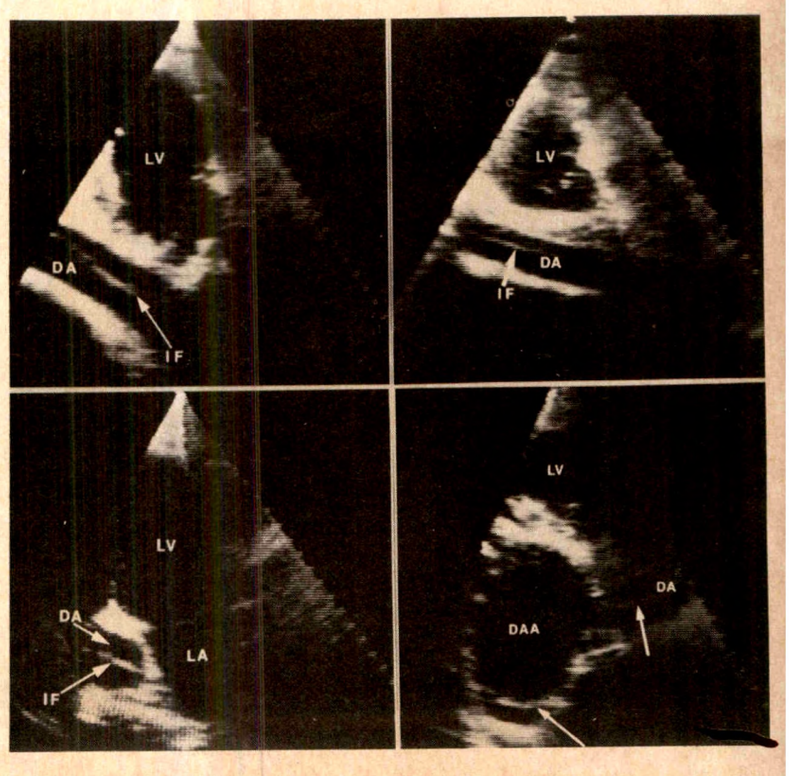

FIGURE 2. Cross-sectional echocardiographic findings in patients with abnormalities of the retrocardiac descending aorta. **Top left,** in Patient 1, an intimal flap (IF) was visualized within the enlarged descending thoracic aorta (DA), which measured 2.9 cm in diameter. **Top right,** an oscillating intimal flap (IF) was visualized within the descending thoracic aorta (DA) of Patient 2. The diameter of the aorta measured only 2.2 cm in this region. **Bottom left,** in short axis the descending thoracic aorta (DA) in Patient 3 demonstrates the intimal flap (IF) which was seen to oscillate reproducibly during systole and diastole. **Bottom right,** in Patient 5, a large saccular descending aortic aneurysm (DAA) is seen to arise from a normal caliber upper descending aorta (DA), which measured 2.2 cm in diameter. The saccular aneurysm measured over 8 cm in diameter. Internal echoes (**white arrows**) within the DA and DAA may have represented intimal flaps suspected on computerized tomography. LA = left atrium; LV = left ventricle. One centimeter markings are displayed on the right side of the sectors.

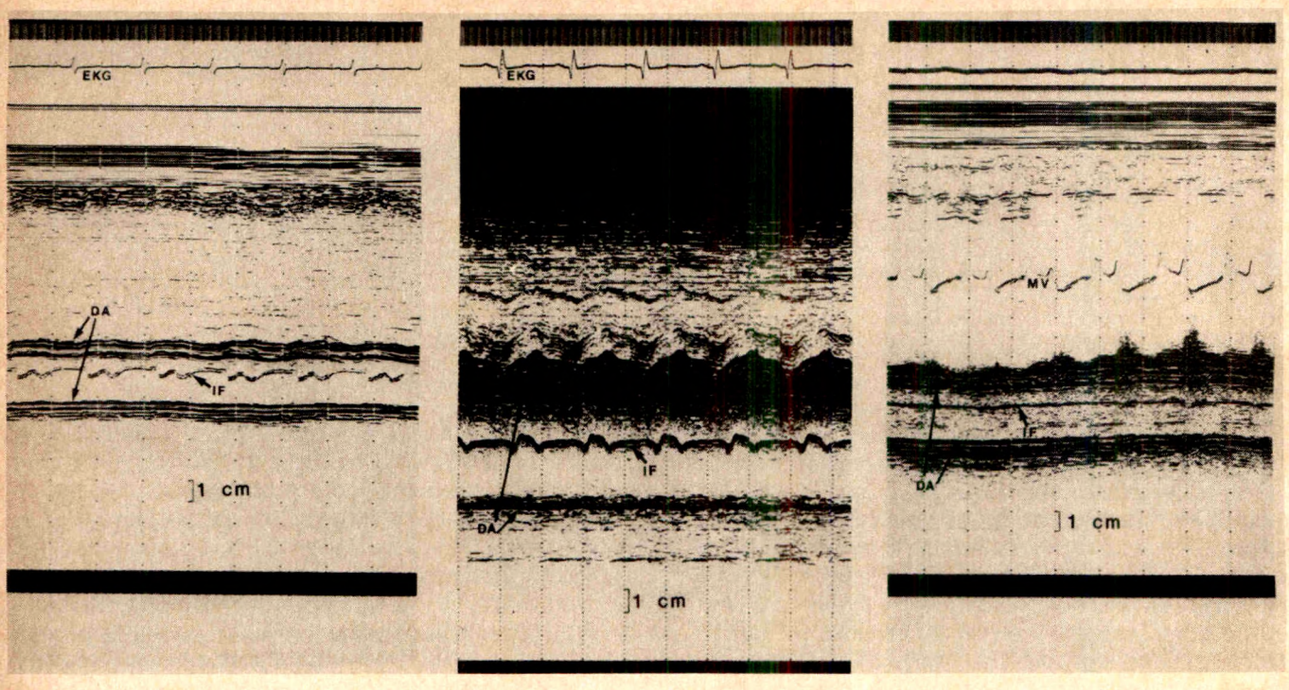

FIGURE 3. M-mode echocardiograms of the descending thoracic aorta (DA) were obtained using the M-mode cursor of the cross-sectional echocardiograph. The internal echoes, almost certainly representing intimal flaps (IF), are seen to have an oscillating pattern of movement in systole and diastole in Patients 2 and 3 (**left and middle**). The movement of the flap is seen to be different from the movement of the aortic walls, presumably reflecting differential rates of filling of the true and false lumens. The aortic walls appear thickened in Patient 2, possibly as a result of a subintimal hematoma. In Patient 4 (**right**), the internal echo is separated from the anterior aortic wall by approximately 1 cm but is nonmoving. EKG = electrocardiogram; MV = mitral valve.

scending aorta when they extend to the retrocardiac region. This technique demonstrated abnormalities in all 5 patients confirmed to have aneurysmal dilatation or aortic dissection, or both, on aortogram or on computerized tomography. With combined echocardiographic examination of the ascending and descending thoracic aorta, all patients with dissection were accurately classified by echocardiographic study as having either DeBakey type 1 or 3 dissections, as compared with results of aortograms, surgical observations, and computerized tomography.

The abnormalities identified, including appreciable dilatation of the aorta and abnormal internal echoes, appear to be quite specific for aortic pathology. Linear stationary or oscillating echoes were not visualized between the anterior and the posterior walls of the aorta in any of the 50 consecutive patients. While not recognized in our control patients, the possibility of false-positive findings in studies for dissection certainly exist. For example, in a patient with excessive thickening of the aortic walls, it is possible that the intima might be visualized as widely separated from the outer wall. In addition, lateral spread of the sound beam in the far field or reverberations could potentially cause the appearance of spurious echoes within the aorta. To diminish the possibility of a false-positive finding, the abnormality should optimally be visualized in short as well as long axis, and reverberations from anteriorly positioned structures should be excluded. Oscillation of an apparent intimal flap during systole and diastole may enable a more specific diagnosis of dissection, since it suggests the presence of true and false lumens, with differential time courses of filling (Fig. 3).

Larger studies are necessary to define further the sensitivity and specificity of echocardiographic techniques in the recognition of all types of aortic pathology. However, this and other previous cross-sectional echocardiographic studies[3–8] suggest that ultrasonic techniques may indeed prove useful in the initial evaluation of patients presenting with symptoms or signs, or both, suggestive of acute or chronic aortic pathology.

Respiratory Effects on Systolic Time Intervals During Pericardial Effusion

DAVID H. SPODICK, MD, DSc, DELORES PALADINO, RN, and ATHAN P. FLESSAS, MD

Pericardial effusion without cardiac tamponade is defined by the detection of excessive pericardial fluid without clinical manifestations, particularly pulsus paradoxus (inspiratory decrease in systolic blood pressure >10 mm Hg) and jugular venous distention. Nineteen consecutive patients without heart or lung disease who had pericardial findings and no evidence of tamponade were investigated by echocardiography: 14 with pericardial effusion and 5 with noneffusive ("dry") pericarditis. Patients with effusion had an inspiratory decrease in left ventricular ejection time (ΔLVET) of 17.9 ± 5.78 ms and an increase in preejection period (ΔPEP) of 12.1 ± 3.78 ms, each well beyond the respective respiratory changes measured in normal subjects. The 5 control patients with dry pericarditis had a mean ΔLVET and ΔPEP of only 8.0 and 7.0 ms, respectively. Of the 14 patients with effusion, 6 whose systolic pressure showed no respiratory change had mean ΔLVET of 13.7 ms and ΔPEP of 11.2 ms, comparable to the other 8 patients with effusion who had a respiratory change of 2 to 10 mm Hg. We conclude that although pulsus paradoxus was not present, excessive pericardial fluid is not physiologically inert. If a satisfactory echocardiogram is not available, exaggerated respiratory fluctuation in systolic time intervals may be evidence of excessive pericardial fluid.

Exaggerated inspiratory reduction in left ventricular function, clinically expressed as pulsus paradoxus (defined as a >10 mm Hg inspiratory decrease in systolic blood pressure during quiet breathing[1]), is a hallmark of cardiac tamponade. In contrast, most pericardial effusions are not accompanied by clinical signs of abnormal cardiac function, including pulsus paradoxus, and so long as an effusion does not significantly compress the heart, invasive measurements are not justified. Indeed, repetitive search at the bedside for pulsus paradoxus is the common means of monitoring effusions for the development of cardiac tamponade. Two reports[2,3] mention 3 patients with pericardial effusion but no tamponade who had marked respiratory changes in left ventricular ejection time of 25 to 50 ms without pulsus paradoxus. These were 3.5 to 7 times the expected mean respiratory change in left ventricular ejection time (LVET) (7.1 ± 2.3 ms) observed in normal subjects and in patients with stable coronary disease.[4,5] Moreover, Carter et al[2] could only induce up to a 10 ms change in ejection time even with "accentuated respiration" in 10 patients free from pericardial fluid.

A greatly exaggerated respiratory change in ejection time due only to the presence of pericardial fluid could have important physiologic, and perhaps diagnostic, implications. Moreover, the effect on the other major systolic time interval (STI), the preejection period (PEP), has not been reported. Because a predictable effect on STI would indicate that in the absence of tamponade, pericardial fluid is not physiologically inert, we wished to determine (1) whether PEP was also affected by nontamponading pericardial fluid, (2) how often the STIs were significantly affected, and (3) the relation of such effects to effusion size.

We studied prospectively the STI in 20 consecutive patients with pericardial disease but without cardiac or pulmonary disease and with a normal, regular breathing pattern demonstrated by thermistor recordings. These included (1) 15 consecutive patients with pericardial effusion who had no signs of cardiac or pulmonary embarrassment, no pulsus paradoxus, and no jugular venous distention, and (2) 5 patients with noneffusive (dry) pericarditis, that is, with absolutely no evidence of pericardial fluid on echocardiogram. (We recognize that >10 mm Hg may be arbitrary for pulsus paradoxus, but it is the generally accepted cutoff.[1])

Methods

Study patients: All patients presenting at the echocardiographic laboratory were screened for pericardial effusion. One patient was excluded after recording because of sinus arrhythmia. Fourteen consecutive patients with detectable pericardial fluid were identified with the following characteristics: (1) pericardial effusion without echocardiographic signs associated with cardiac tamponade,[6] (2) respiratory variation of ≤10 mm Hg in brachial artery systolic pressure (measured by cuff in the echocardiography laboratory), (3) no jugular venous distention, (4) electrocardiogram showing

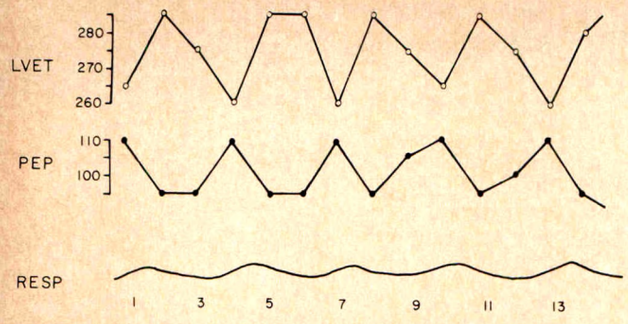

FIGURE 1. Beat-to-beat fluctuation in left ventricular ejection time (LVET) and preejection period (PEP) in a 67-year-old woman with rheumatoid arthritis and moderate-sized pericardial effusion. RESP = thermistor tracing, inspiration upward. Minimal LVET and maximal PEP occur very close to peak inspiration.

stable sinus rhythm without significant respiratory changes, (5) absence of respiratory disease or disordered breathing patterns and subsequently a clear second heart sound in phonocardiograms. Graphic recordings were made on an Irex System II recorder using Leatham suction microphones with filter adjustments to record optimal second heart sounds.

Study protocol: Immediately after echocardiography established the presence of pericardial effusion, patients were investigated by recording at a paper speed of 100 mm/s: (1) phonocardiogram at a position to clearly register the aortic component of the second heart sound (usually left midsternal border), (2) right carotid displacement pulse, and (3) phasic breathing changes through a thermistor sensor. The preejection period and left ventricular ejection time were measured in milliseconds in continuous respiratory cycles with technically good waveforms. The timing of II_A (q − II_A) was taken as electromechanical systole (EMS). Left ventricular ejection time was calculated by subtracting q − CARu from q − CAR_{In}. The PEP was obtained by subtracting LVET from EMS: that is, PEP = EMS − LVET.[7]

To minimize bias, measurements were made without reference to the respiratory trace. Heart rates were measured by cycle-to-cycle measurements of R-R intervals in milliseconds and expressed as beats per minute. After all measurements were completed, the respiratory tracing was correlated and minimal and maximal ejection and PEPs (expressed to the nearest 5 ms) were determined for each patient for each respiratory cycle.

TABLE I Respiratory Change

Effusion: Echocardiographic Estimate	n	Mean ΔPEP (ms)	Mean ΔLVET (ms)	Range ΔSyst BP (mm Hg)
Minimal to small	3	10.0	11.7	0–10
Moderate	5	12.0	22.0	0–10
Moderately large to large	6	13.7	17.5	0–8
Total (mean ± SD)	14	12.3 ± 3.78	17.9 ± 5.78	0–10
Controls (dry pericarditis)	5	7.0 ± 2.73	8.0 ± 2.73	0–4
Effusion patients with ΔSyst BP = 0	6	11.2	13.7	0

ΔLVET = inspiratory decrease in left ventricular ejection time; ΔPEP = increase in preejection period; ΔSyst BP = change in systolic blood pressure; SD = standard deviation.

A separate observer, with no knowledge of any other findings, evaluated the echocardiograms without reference to the other findings to estimate the amount of pericardial fluid[6] in the following ranges: minimal, small, moderate, moderately large, and large. The following criteria were used: *minimal:* all fluid posterior and appearing only during systole or systole and early diastole; *small:* all fluid posterior, appearing throughout systole and diastole and <10 mm deep; *moderate:* all fluid posterior with wide (≥10 mm) separation of epicardium from parietal pericardium with or without a trace of fluid anteriorly; *moderately large:* posterior fluid plus up to 5 mm anterior fluid; and *large:* posterior fluid plus anterior fluid ≥10 mm. More quantitative estimation was avoided because of serious inaccuracies using M-mode echocardiography.[6]

Patients with dry pericarditis were identified by a typical pericardial rub with typical or atypical[8] electrocardiographic changes, in the presence of a syndrome consistent with acute pericarditis, and by echocardiograms showing no fluid. The foregoing procedure for STI and respiratory tracings was followed.

Results

Fourteen consecutive patients with pericardial effusion and 5 consecutive patients with dry pericarditis were investigated. The same directional changes occurred in every patient: maximal preejection period and minimal ejection time always occurred in beats at or closest to peak inspiration (Fig. 1). Heart rates ranged between 64 and 122 (mean 91.5 beats/min). Heart rate change during respiration was minimal, making it unnecessary to rate-index the ejection time.

Results are summarized in Table I. By protocol, no patient had a respiratory change in blood pressure of >10 mm Hg. In fact, only 2 patients had a 10 mm Hg decrease in systolic blood pressure; 4 had a 6 mm Hg decrease and 1 each had 7 and 8 mm Hg inspiratory decreases in systolic pressure. Six had no detectable respiratory change. Because of the small numbers, the individual judgments of effusion size were consolidated in 3 final categories, resulting in 3 patients with minimal to small effusions, 5 with moderate effusion, and 6 with moderately large to large effusions.

Table I shows a mean inspiratory increase in the preejection period (ΔPEP) of 12.3 ms with a small standard deviation and very little difference according to size of the effusion. The mean inspiratory decrease in left ventricular ejection time (ΔLVET) was larger, being 17.9 ± 5.78 ms. The largest mean ΔLVET was in moderate sized effusions, of 22.0 ms; the smallest ΔLVET was in the minimal to small group (11.7 ms). (Because of the relatively small size of each subgroup, statistical tests were not applied to subgroup differences.) In contrast, patients with dry pericarditis had mean changes in left ventricular ejection time of 8.0 ms and in the preejection period of 7.0 ms.

Discussion

Normal ambulatory subjects and stable coronary patients without pericardial disease have very small respiratory changes in left ventricular ejection time (mean ± standard deviation [SD] 7.1 ± 2.3) and in the preejection period (mean 4.2 ± 3.3 ms), respectively.[4,5] In the absence of pericardial fluid, even "accentuated

breathing" could only induce LVET changes up to 10 ms.[2] With nontamponading pericardial effusion, respiratory changes in each of these measurements clearly tend to be greater despite the absence of pulsus paradoxus. (Indeed, separate measurements in the 6 patients with no detectable respiratory change in systolic blood pressure [Table I] showed that ejection and preejection period changes were entirely comparable to those of the whole group: mean ΔLVET 13.7 ms; mean ΔPEP 11.2 ms.) It is also clear that the mean changes were greater than those in the 5 control patients with dry pericarditis, who had respiratory changes in ejection time comparable to those of the normal subjects and coronary patients previously reported.[4,5]

Because hemodynamic measurements were not made in these patients, mechanism-related explanations of the results necessarily remain speculative, although consonant with known physiologic events. The directional changes in the preejection period and left ventricular ejection time were those expected in response to reduced volume load (and, hence, preload) in the left ventricle. Because LVET is nearly always 2.5 to 3.5 times the duration of the preejection period, and the mean respiratory change in ejection time only about 1.5 times that of the preejection period, the relative change in the preejection period is much larger than that in the ejection time. These disproportionate changes are not surprising because a relatively greater change in preejection period is characteristic of many conditions with beat-to-beat changes in left ventricular filling such as atrial fibrillation, varying atrioventricular block, ectopic beats, and postectopic augmented beats.[9]

The findings in this investigation have several implications which ethically could only be studied noninvasively because "innocent" pericardial fluid made invasive procedures, such as pericardiocentesis, and vascular or cardiac catheterization unjustifiable in these patients. (In none did tamponade subsequently develop.) Yet, the changes indicate that the presence of apparently noncompressing pericardial effusion does not mean that the fluid lacks influence on cardiovascular physiology. The fact that cuff blood pressure could not identify pulsus paradoxus within the common definition of that term (indeed, 6 patients with no change in blood pressure had LVET and PEP changes comparable to those of the whole group) does not mean that the fluid was inert or even that its pressure was nil. Depending on the elasticity of the parietal pericardium, a critical but individually variable amount of fluid could cause intrapericardial pressure to increase slightly but significantly during inspiration. Normally and also during pericardial effusion and tamponade, pericardial pressure decreases during inspiration, paralleling pleural pressure. This accelerates caval blood flow into the right heart, and the right ventricle expands producing a secondary increase in pericardial pressure. During tamponade, that expansion increases inspiratory compression of the left ventricle, producing a greater than normal decrease in left ventricular input and, hence, output—pulsus paradoxus. Indeed, during experimental tamponade, if inspiratory right heart filling is prevented, pulsus paradoxus is absent.[1] Our patients' clinically noncompressing pericardial effusions may represent an intermediate state in which comparable mechanics occur to a lesser degree and affect other, perhaps more sensitive, expressions of function, that is, the STI. (Our patients also did not have the gross septal shift seen with pulsus paradoxus.) Group differences based on effusion size alone may not show smooth gradations because of an unmeasurable element: interpatient variability in stiffness of the parietal pericardium, including changes related to duration and rate of accumulation of effusion (unknown quantities). Thus, in Table I, ΔLVET was greater for moderate than for large effusions, perhaps for this reason.

Simultaneously decreasing LVET and increasing PEP are characteristic effects of decreasing preload.[3,9] Exaggeration of corresponding expected respiratory changes in LVET and PEP are most consistent with greater than normal inspiratory decrease in left heart filling,[1] that is, preload. Indeed, Janicki et al[10] recently showed that the filling gradient between pulmonary veins and left ventricle is especially sensitive to the presence of pericardial fluid over a wide range of pericardial pressures from −3 to +20 mm Hg, implying responses at quite low levels of intrapericardial pressure change. Excessive respiratory changes in STI with nontamponading effusions are consistent with these observations. Moreover, because such changes were not present with "dry" pericarditis, this implies that (1) irrespective of whether our patients' effusions did not compress the heart, invasive procedures not being indicated, the fluid was not physiologically inert; (2) abnormal respiratory changes in blood pressure, at least by cuff, may be less sensitive than STI to the physiologic effects of nontamponading fluid; (3) in the absence of satisfactory echocardiographic tracings, the degree of respiratory fluctuation in STI may provide evidence for or against excessive pericardial fluid as a component of an enlarged cardiac silhouette.

Usefulness of Echocardiographic Right Ventricular Measurements in Estimating Right Ventricular Hypertrophy And Right Ventricular Systolic Pressure

RAVI PRAKASH, MD and HARUO MATSUKUBO, MD

Right ventricular wall thickness (T) measurements were made in 111 patients by echocardiography to evaluate their usefulness in diagnosing right ventricular hypertrophy (RVH) and in predicting right ventricular peak systolic pressure (P). Anatomic and echocardiographic findings of RVH were compared in 36 of 111 subjects: diastolic T (dT) and systolic T (sT) had a sensitivity of 90 and 34% and a specificity of 94 and 100%, respectively, in the diagnosis of RVH. Echocardiographic and hemodynamic findings were compared in the remaining 75 of 111 patients undergoing cardiac catheterization: dT was 6.5 ± 2.7 mm in 46 patients with elevated P (58.2 ± 30.2 mm Hg) versus 3.8 ± 0.9 in 29 patients with normal P (26.3 ± 2.7 mm Hg) ($p < 0.01$). The dT and P had a linear correlation ($r = 0.92$) in 40 patients with right ventricular end-diastolic dimension <13 mm/m^2. Estimates of P in 22 patients with atrial septal defect and right ventricular end-diastolic dimension >13 mm/m^2 were fairly good ($r = 0.83$). It is concluded that echocardiographic measurements of T are useful in diagnosing RVH and in estimating P.

Echocardiographic measurements of right ventricular wall thickness (T) were first made and reported in children.[1–3] Recently, echocardiographic recordings of the right ventricular wall were obtained by several investigators by the subxiphoid and anterior parasternal techniques[5–12] in adult patients with congenital heart disease,[3,4] in athletes,[5] in patients with amyloid cardiomyopathy,[6] in normal subjects,[7] and in patients with myocardial infarction.[8] Furthermore, measurements of diastolic T(dT) have also been useful in the diagnosis of right ventricular hypertrophy (RVH) in adults.[9] In this report we attempt to answer the following questions: Are the echocardiographic measurements of T useful in the diagnosis of RVH? Does a good correlation exist between the echocardiographic T and the right ventricular peak systolic pressure (P)? Can P be predicted from measurements of T?

Methods

A total of 111 subjects aged 12 to 87 years were studied. The patient population included 23 patients with coronary heart disease, 22 with atrial septal defect, 20 with mitral valvular disease, 12 with combined mitral and aortic valvular disease, 11 with cardiomyopathy, 5 with hypertension, 3 normal subjects, 3 with aortic valve disease, 2 with chronic obstructive pulmonary disease, 2 with pentalogy of Fallot, 1 with tetralogy of Fallot, 4 with pulmonary stenosis, 1 with primary pulmonary hypertension, and 2 with ventricular septal defect. Necropsy measurements of T were made in 36 of the 111 patients who died within 1 month of the echocardiographic study. The remaining 75 patients underwent right heart catheterization.

Echocardiographic technique: *Anterior parasternal approach:* Echocardiograms were recorded on a strip chart recorder (Smith Kline Instruments, Toshiba Sonolayergraph model SSH 10A, or Aloka SSD-90 recorders) in M-mode using a 2.25 MHz transducer from the left fourth intercostal space in supine position. It was necessary to carefully adjust the near gain, coarse gain, and depth compensation controls to record a clear right ventricular wall.[10] The T was measured in a plane where the interventricular septum and the posterior left ventricular wall were seen below the level of the mitral valve. The right ventricular end-diastolic dimension (D) and the dT were measured at the beginning of the QRS on the electrocardiogram and the systolic right ventricular wall thickness (sT) was measured where the thickness of the right ventricular wall was at its greatest (Fig. 1). The right ventricular wall

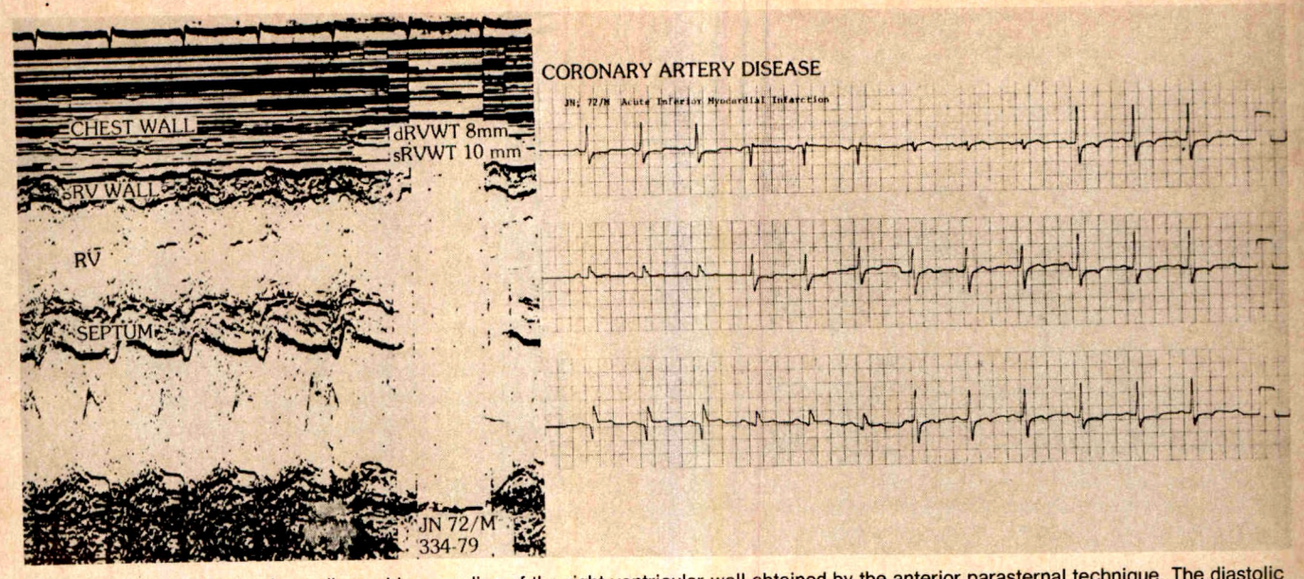

FIGURE 1. An untouched echocardiographic recording of the right ventricular wall obtained by the anterior parasternal technique. The diastolic (dRVWT) and systolic right ventricular wall thickness (sRVWT) in this echocardiogram are 8 and 10 mm, respectively, and meet the echocardiographic criteria for the diagnosis of RVH. The right ventricular end-diastolic dimension is also abnormal and measures 33 mm. This 72-year-old man had had an acute anterior wall myocardial infarction and manifested right ventricular failure. The diagnosis of RVH is not clear-cut in this 12-lead electrocardiogram.[10,18] Two subtle signs suggestive of RVH are present: (1) S_1,Q_3 (sensitivity 25% and specificity 87%), and (2) SV_5 and SV_6 (sensitivity 58% and specificity 53%).[18]

echoes move away from the transducer during systole. Five beats were separately measured to obtain an average T. The T is the distance between the epicardium and the endocardium of the right ventricular wall and the measurements were made by the leading edge method. The echoes were not read blindly, and the clinical diagnosis was known in most cases. At the same preselected location, T was measured by 2 observers in 25 patients; the difference in the measurements of the T was ≤1 mm. Measurements of T by the same individual on 2 different occasions showed a variation of 0.1 to 0.3 mm in 25 patients. Each 1 cm mark on the echocardiographic tracing was divided into 10 or more equal parts to increase the accuracy of the measurements. The final reported measurement was rounded to the closest millimeter. All tracings were made during normal quiet breathing.

Subxiphoid approach: The transducer was placed on the subxiphoid area and directed posteriorly, superiorly, and to the left.[11] With the septum as a landmark, the orientation of the transducer was adjusted to obtain excellent visualization of the right ventricular wall. Echoes from the chordae tendineae attaching to the tricuspid leaflets were frequently visualized; they can easily be misidentified as the endocardium. This can be avoided by the use of contrast method during an M-mode scan. Figure 2 shows that echoes produced by contrast dye are demonstrated not to enter between 2 parallel echoes identified as the right ventricular wall, thus proving a definite visualization of the endocardium.

Right heart catheterization: Seventy-five subjects underwent diagnostic right heart catheterization within 1 week of the echocardiographic examinations. In this study the patients were considered to have right ventricular pressure overload when the P was ≥31 mm Hg. T was measured by the subxiphoid as well as the anterior approach in these patients.

Necropsy technique: At necropsy, the hearts were dissected in a uniform manner and the T measurements were made without knowledge of the echocardiographic measurements. T was measured in millimeters with a ruler, in the midportion of the free wall of the right ventricle (between the base and the apex).[12] Sections were carefully made to avoid the valleys between the trabeculations. The normal T at necropsy is 2 mm, and RVH is present when the T is ≥5 mm.[13–16] Thus, a 5 mm thick right ventricular wall at necropsy was considered diagnostic of RVH.[9,13–16] Twenty patients had no RVH as T at necropsy was ≤4 mm, and 16 patients had RVH as T was ≥5 mm at necropsy.

Statistical analysis was performed using standard least-squares linear regression analysis and Student's *t* test.

Results

Echocardiographic and necropsy correlation: The echocardiographic dT was 3.3 ± 0.6 mm (range 2 to 4) in patients with no RVH versus 5.9 ± 0.9 mm (range 5 to 8) in RVH patients ($p < 0.01$): dT ≥5 mm had a sensitivity of 90% and a specificity of 94% in diagnosing RVH. The sT was 5.1 ± 1.5 mm in patients with no RVH versus 9.1 ± 2.9 mm in patients with RVH ($p < 0.01$): sT ≥10 mm had a sensitivity of 34% and a specificity of 100% in diagnosing RVH.

Echocardiographic and hemodynamic correlation: Of the 75 patients undergoing right heart catheterization, 29 did not have right ventricular pressure overload (mean P 26.3 ± 2.7 mm Hg) and 46 patients had right ventricular pressure overload (mean P 58.2 ± 30.2 mm Hg) ($p < 0.01$). T was 3.8 ± 0.9 mm in patients without and 6.5 ± 2.7 mm in patients with right ventricular pressure overload ($p < 0.01$) (Fig. 3). P was ≤30 mm Hg in 23 of 30 patients with dT of 2 to 4 mm and was increased in all 11 subjects with dT ≥8 mm. P was 43, 74, and 91 mm Hg in 3 patients with dT of 8 mm; 84 and 110 mm Hg in 2 patients with dT of 9 mm; and 100,

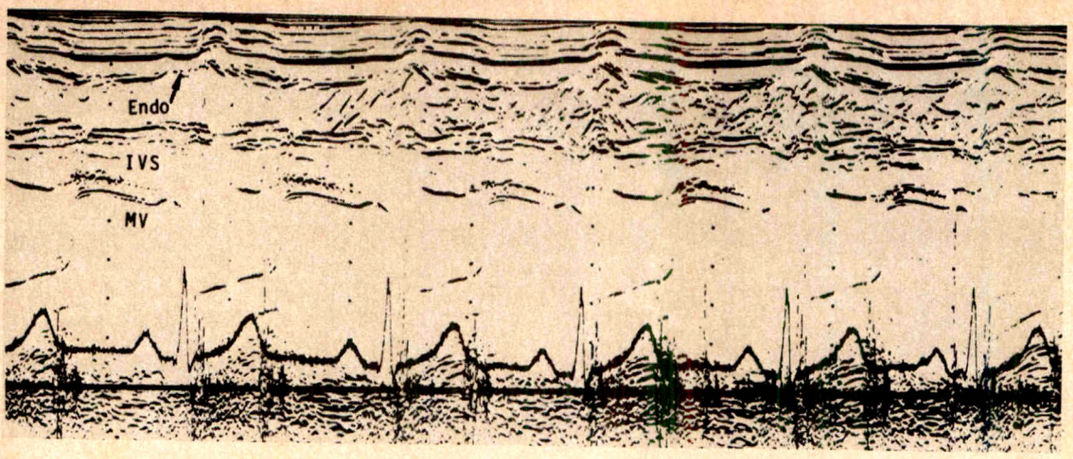

FIGURE 2. Contrast method for identification of the endocardium (Endo). The echoes produced by the contrast medium are seen in the right ventricular cavity and do not enter the space between the 2 parallel echoes of the right ventricular wall representing the endocardium (directly in contact with the contrast) and the epicardium. IVS = interventricular septum; MV = mitral valve.

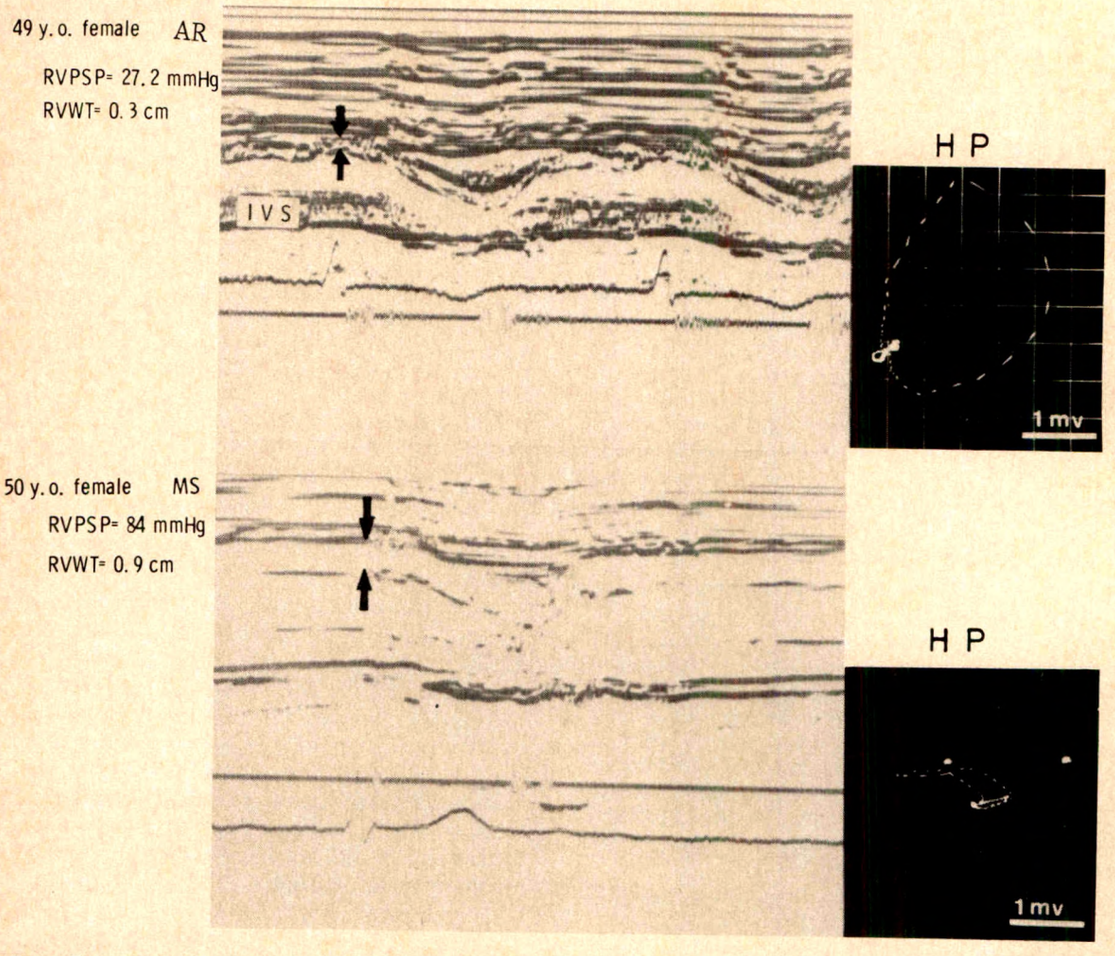

FIGURE 3. Recordings of the right ventricular wall obtained in 2 patients are shown along with their vectorcardiograms. The **upper panel** shows that the diastolic right ventricular wall thickness (RVWT) measured 3 mm in this 49-year-old woman with aortic regurgitation (AR). Right ventricular peak systolic pressure (RVPSP) was 27.2 mm Hg and the vectorcardiogram shows left ventricular hypertrophy. In the **lower panel** the RVWT is 9 mm. There is also evidence of RVH (type C) on the vectorcardiogram in this 50-year-old woman with mitral stenosis (MS). RVPSP was 84 mm Hg. HP = horizontal plane of the vectorcardiogram; IVS = interventricular septum.

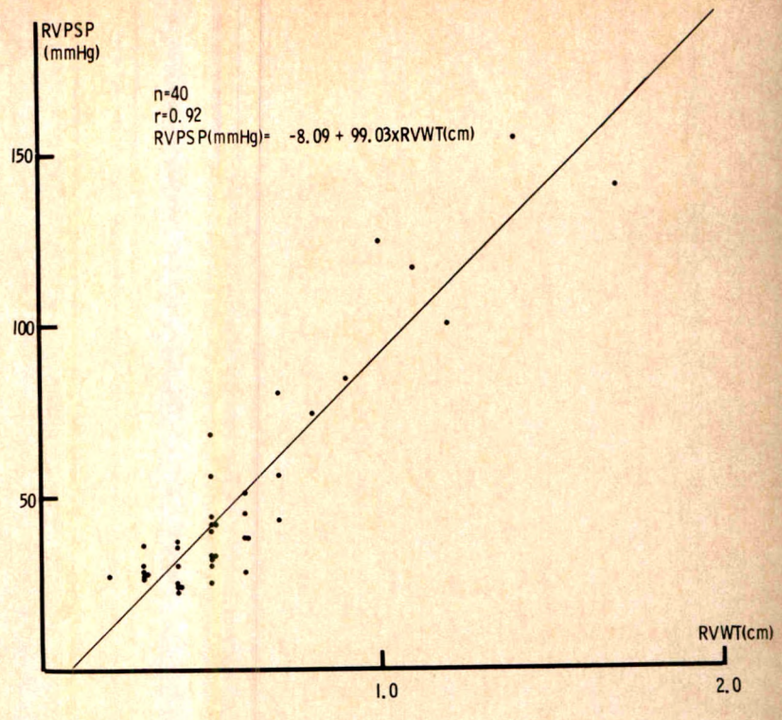

FIGURE 4. Correlation between the right ventricular peak systolic pressure (RVPSP) and the diastolic right ventricular wall thickness (RVWT) measured by echocardiography is shown in 40 patients with a right ventricular end-diastolic dimension index ≤ 12 mm/m^2 and was good ($r = 0.92$). The following regression equation was obtained: RVPSP (mm Hg) = $-8.09 + 99.03 \times$ T (cm).

124, 116, 140, 154, and 82 mm Hg in 6 patients with dT $\geq$10 mm. Measurements of T were correlated with P, and the correlation coefficient (r value) for the 75 patients was 0.89.

The role of D was then examined in relation to T and P. The 75 patients were divided into 2 groups on the basis of D $\geq$13 mm/m^2. Forty patients had D <13 mm/m^2 (mean 8.7 $\pm$ 2.2 mm/m^2), and 35 patients had a dilated right ventricle with a mean D of 19.5 $\pm$ 5.8 mm/m^2. As might be expected, all 22 patients with atrial septal defect had a dilated right ventricle (D $\geq$13 mm/m^2). Measurements of T were found to have a good linear correlation with P ($r = 0.92$) in patients with D <13 mm/m^2 (Fig. 4). The following regression equation was obtained: P (mm Hg) = $-8.09 + 99.03 \times$ T (cm). The standard error of the pressure estimates (SEE) was 13.2 mm Hg. Using this equation, we tried to predict P in 35 patients with D $\geq$13 mm/m^2. In 22 patients with atrial septal defect, the slope of the regression between the predicted and measured P was 1.03, with a correlation coefficient of 0.83. Only 1 patient with atrial septal defect fell out of the 1 SEE. However, of the remaining 13 of 35 subjects with D $\geq$13 mm/m^2 and no atrial septal defect, 5 fell out of the 1 SEE, although only 1 of the 2 SEE (Fig. 5).

Discussion

As echocardiographic measurements of T are useful in diagnosing RVH and predicting P, it is important to examine the feasibility of the echocardiographic technique for obtaining right ventricular wall recordings. High quality echocardiographic tracings were obtained in 90% of infants and children up to 18 years of age by Arcilla and associates.[3] A yield of over 80% has been reported with the anterior parasternal approach[7,9,10,12] and over 90% with the subxiphoid technique in adults.[11] The best way to record the right ventricular wall by echocardiography was prospectively investigated in 40 consecutive adult subjects (normal subjects and patients with congenital and acquired cardiac disease) by Tsuda et al.[7] The highest successful recording rate was 80% and was achieved by an anterior approach from the left sternal border in the supine position: the yield with the subxiphoid approach was 50%.[7] These studies confirm our experience that it is feasible to obtain echocardiographic right ventricular wall recordings in adults.

In the present study, the dT measured 3.8 $\pm$ 0.9 mm in cardiac patients without right ventricular pressure overload, 3.3 $\pm$ 0.6 mm in patients with no RVH at necropsy, 6.5 $\pm$ 2.7 mm in patients with right ventricular pressure overload, and 5.9 $\pm$ 0.9 mm in patients with RVH at necropsy. The mean dT in normal subjects was 2.4 $\pm$ 0.5 mm in the study of Tsuda et al[7] using the anterior approach and 3.4 $\pm$ 0.8 in the study of Matsukubo et al[11] using subxiphoid approach. RVH as indicated by an increased dT has also been found in patients with right ventricular volume and pressure overload, in male and female long-distance runners,[5] and in patients with amyloid cardiomyopathy.[6] The dT and sT had a sensitivity of 90 and 34% and a specificity of 94 and 100%, respectively, for diagnosing RVH.

The correlation coefficient (r value) between dT and P in all 75 patients was 0.89, but improved to 0.92 when correlation between dT and P was determined only in the 40 patients with D <13 mm/m^2. P could be predicted accurately in all patients with D <13 mm/m^2 as

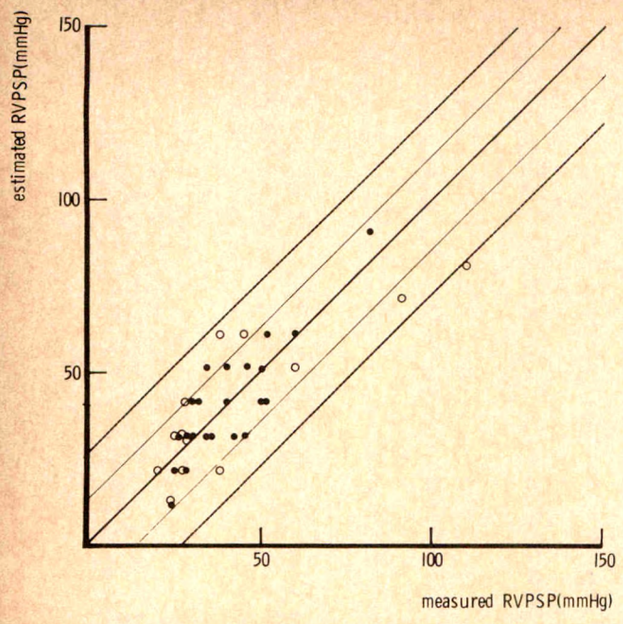

FIGURE 5. Correlation between the measured right ventricular peak systolic pressure (RVPSP) and the estimated values of P calculated from the regression equation. **Closed circles** denote patients with atrial septal defect and **open circles** denote the remaining subjects with DI >1.3 cm/m^2. A fair correlation is seen in patients with atrial septal defect, the slope of the regression between the predicted and measured P was 1.03, the correlation coefficient was 0.83, and only 1 patient fell out of line representing 1 SEE. In the remaining 13 patients, P was not accurately predicted.

well as in patients with atrial septal defect with D >13 mm/m^2. However, in the remaining 13 patients with no atrial septal defect and D >13 mm/m^2, P could not be accurately predicted, possibly for the following reasons: (1) The value of P was overestimated in a 50-year-old woman who underwent mitral commissurotomy 16 months before the present investigation. Overestimation may have been due to failure of the RVH to regress postoperatively; P was 65 mm Hg before operation and 37 mm Hg during the current study. (2) By combined use of the subxiphoid 2-dimensional and M-mode techniques, we confirmed that the echocardiographic beam normally passes through the midportion of the free wall of the right ventricular inflow tract and the degree of RVH is uniform in most cases of atrial septal defect. However, the degree of RVH differed from the base to the apex of the right ventricular inflow tract in 2 patients, 1 with tetralogy of Fallot and the other with primary pulmonary hypertension. Therefore, a change in the angulation of the transducer may result in an error in the estimation of the true thickness of the right ventricular wall when RVH is not uniform. (3) Moreover, the pulmonary arterial systolic pressure can change in some patients with right ventricular pressure overload because of changes in heart rate, respiration, and ventricular contractility, as was observed by us in 1 patient (34-year-old woman) with mitral stenosis and regurgitation.

BLIND REVIEWS

This letter offers a brief comment on your recent statements concerning blind reviews. Although the motivation for impartiality in reviewing scientific manuscripts is well understood, my experience as both an author and a reviewer supports the side of nonblind reviews. The weight of my opinion rests on one crucial point. As an author, it is important to me to make clear to the reader which aspects of my results or my discussion are based on previous work in my or my colleagues' laboratories. I generally attempt to clearly identify for the reader those parts of the discussion that refer to work performed in our institution. The reader needs to clearly understand how much of the case being made has been built up in one environment and how much derives its foundation from various institutions. It is unfair to deny a reviewer that information.

Typically, a reviewer would appreciate a clear understanding of the extent of the author's background in the area being investigated and whether methods used or conclusions drawn are founded in well-experienced laboratories. In addition, little effort is required by the reviewer to determine the source of an article even in a blind review. Unfortunately, some reviewers are unfairly prejudiced against a particular investigator or investigators. However, individuals who apply such partialities will go to the necessary effort to identify the source of a given article. Normally, a brief review of the reference list will clearly identify the source. Therefore, blind reviews will generally not prevent such prejudicial refereeing.

The position of editor is a difficult one. For my own work, I will submit my articles clearly identified with their source and will request nonblind reviews. I will also urge my colleagues to do the same. Time will prove that the only means to prevent prejudiced reviews is to clearly document them and to eliminate those reviewers from your list. Your open approach to this problem and the editorial policy that allows contributing authors to choose the manner in which their particular manuscript is reviewed is greatly appreciated.

Michael D. Devous, Sr., MD
Dallas, Texas

I read of your intention to initiate blind reviews for manuscripts submitted to your *Journal*. I think this is an excellent idea which not only may offer a greater equity with respect to acceptance of papers but also may allow the opportunity to determine whether reviewer bias exists.

If possible, it would be important to submit each manuscript for both a "blind" and a "standard" review. An additional step would be to have 2 "standard" reviewers: 1 prominent in the field addressed by the author, the other with competence in another area of cardiology. I realize that the review process, at best, is somewhat subjective, requiring a large number of reviewers to be involved before a meaningful conclusion is reached concerning reviewer bias. However, the volume of manuscripts submitted to the *Journal* could provide for sufficient numbers if the extra work would not be a great burden.

Barry Stimmel, MD
New York, New York

Since you asked for comments on this issue, I would point out that as long as the policy for blinded reviews remains optional, there clearly is an advantage for more established and well-known investigators or laboratories to remain identified, while there is an incentive for less well-known and established investigators to remain unidentified. Accordingly, reviewers receiving unidentified manuscripts may have a tendency to presume they come from less well-known centers and thus may grade them more harshly than they would manuscripts from well-known investigators or centers. It seems, therefore, that for the blind review policy to work as intended all reviews must be blinded, and that this cannot be an optional policy on the part of either editors or investigators.

ENHANCEMENT OF LEFT VENTRICULAR FUNCTION BY GLUCOSE-INSULIN-POTASSIUM IN ACUTE MYOCARDIAL INFARCTION

I read with great interest the report, "Enhancement of left ventricular function by glucose-insulin-potassium in acute myocardial infarction," by Whitlow et al. I consider the report excellent, but an injustice is evidently manifested. No reference is made to the work of Demetrio Sodi-Pallares, a pioneer in the investigation of glucose-insulin-potassium solutions.

Sodi-Pallares demonstrated a marked improvement in reduced myocardial contraction at the center of a recent myocardial infarction with glucose-insulin-potassium solutions. The study was performed in 1964 with the strain gauge method (Brodie bridge) and was described in the book, "Ischaemic Heart Disease and Polarizing Treatment. New Metabolic and Thermodynamic Bases," published by Tampa Tracings in 1976.

David Contreras, MD
Juarez, Mexico

REPLY: We are certainly cognizant of the pioneering work of Demetrio Sodi-Pallares and his colleagues in the investigation of glucose-insulin-potassium infusion. Indeed, at our institution, interest in glucose-insulin-potassium infusion began after a lecture on the subject here by Dr. Sodi-Pallares. His work has been referenced in many of our previous publications on this subject,[1–4] all of which were included in our manuscript. The lack of direct reference to the work of Dr. Sodi-Pallares and his colleagues in our most recent report in this Journal[5] was certainly not a comment on the quality and importance of their work. We certainly share their enthusiasm in the use of glucose-insulin-potassium infusion in the setting of acute myocardial infarction.

GERONTOLOGIC PHARMACOLOGY

We would like to bring to the attention of the scientific research community a recent report[1] of a workshop on gerontologic pharmacology and of a National Institute on Aging Pharmacology Program announcement[2] based on its recommendations. It has been widely reported that the elderly have a greater incidence of adverse side effects of drugs and of drug interactions than do young adults. Evidence has been reported of altered patterns of drug distribution and responsiveness in the elderly. Because drugs are generally tested in young adults and dosage adjusted to their needs, it is not surprising that the elderly may respond differently. Much research is needed to determine where age-related alterations in drug responses exist and, when found, to determine their cause or causes. Studies are encouraged in both clinical and basic research areas. The addition of cohorts of elderly to ongoing studies may be an appropriate means of detecting significant differences, and special National Institute on Aging programs are available for the performance of pilot studies.

STATE OF MARYLAND PACEMAKER EXPERIENCE (1979–1980): CONFLICTING VIEWS REGARDING THE FREQUENCY OF UNNECESSARY PACEMAKER IMPLANTS

In their article in the January 1, 1983 issue,[1] Scherlis and Dembo report the results of a study that attempts to refute our report on unnecessary pacemaker implants in Maryland. Before raising specific objections to this article we would like to briefly summarize the purpose, findings, and conclusions of our study.

Using the diagnoses the attending physician listed on the face sheets of the charts of all Maryland patients who were given permanent pacemakers in 1979 and 1980, we attempted to determine whether or not there was adequate justification for pacemaker implantation. We identified 7 diagnoses that we considered adequate justification for pacemaker implantation and 9 others that were possible justifications only under appropriate circumstances. A patient with at least 1 of the 7 justifiable diagnoses listed on the face sheet of the medical record was considered an "appropriate" candidate and a patient with at least 1 of the other 9 diagnoses was considered a "questionable" candidate for a pacemaker. A patient that lacked at least 1 of the 16 diagnoses was considered to have been given a pacemaker unnecessarily.

In choosing this methodology we were aware of its limitations. We knew that determining the need for a pacemaker is an inexact science and that need cannot always be determined strictly by reference to diagnoses. We also knew that additional information contained within the medical records would result in crossovers from 1 category to another (for example from "unnecessary" to "appropriate" or vice versa), and we clearly pointed this out in the report. For this reason we were very liberal in our allowable criteria. For example, any patient with a diagnosis of syncope was considered an appropriate candidate for permanent pacing even though this diagnosis may not have been causally related to a cardiac arrhythmia. In essence, we gave the physician the benefit of the doubt at almost every turn.

As reported by Scherlis and Dembo, our study found that in 1979 and 1980, 23% of the pacemakers implanted in Maryland patients were not justified by the diagnoses contained on the face sheet of the medical record. An additional 13% were found to be "questionable" and the remaining 64% were considered "appropriate."

Based on these findings we made 2 recommendations. First, we recommended that the Health Care Financing Administration, which through Medicare pays for approximately 80% of the permanent pacemakers implanted in Maryland, require a second opinion as a condition of reimbursement. We also suggested that Professional Standards Review Organizations (PSROs) establish criteria for pacemaker insertion and review the implants performed at the hospitals under their jurisdiction to ensure that these devices are implanted for appropriate reasons. Neither of these 2 recommendations is extreme; indeed, they would not only reduce the incidence of unnecessary implantations but also educate physicians on appropriate indications for pacing.

In response to our study, Scherlis and Dembo criticized our method and, at the same time, attempted to determine the actual incidence of unnecessary pacemaker implantation in Maryland via chart review. They ultimately determined that unnecessary implantations accounted for 1.4% of all implantations. We think they failed to prove anything of the kind.

While attacking our method as flawed, Scherlis and Dembo fail to acknowledge the obvious bias inherent in the method they employed. As reported by them, each hospital was asked to examine the medical records of patients we labeled unnecessary or questionable recipients of pacemakers to determine whether any diagnosis we identified as justifying implantation, but which was not on the front sheet, was contained in the chart. The clear tone of the letters soliciting the hospitals' cooperation was that this review was to be used to rebut the findings of our study. In fact, the letters to the hospitals from Dr. Scherlis stated explicitly that "(t) here is serious concern as to whether or not the front sheet adequately reflects the complete medical information and justification for pacemaker implantation." It should be apparent that in this context individual hospitals cannot be relied upon to objectively review the medical records of their own pacemaker recipients. The hospitals' bias is overwhelming, and the study fails to take any steps to control for this. The study establishes no guidelines for reviewer selection, the reviewers are not blinded to the purpose of the study, and there are no controlled reviews of even a few randomly selected charts.

Furthermore, as mentioned earlier, our study clearly stated that an examination of the medical records of those patients flagged as "unnecessary" or "questionable" would show that some of them actually needed pacemakers. However, the converse is also true; a number of patients we deemed appropriate candidates for pacing, some based solely on a diagnosis of syncope, probably did not need permanent pacemakers. Scherlis and Dembo did not examine this group. Apparently, they simply assumed that these implantations would have been found appropriate by the chart review method they employed. Thus, they used a double standard, using their own review to change the results with which they disagree, and using our review to sustain the results with which they agree. This is a medically and statistically unacceptable method. As a result, their conclusion that only 1.4% of the permanent pacemakers implanted "might be considered unnecessary or questionable" is simply not valid.

Even more important, however, is the failure of the "chart review" used in the Scherlis and Dembo study to establish standard definitions for such diagnoses as "complete heart block" and "sick sinus syndrome." This is crucial if the need for a pacemaker is to be definitively determined by means of a chart review. For example, while transient atrioventricular block during the postoperative period would be recorded in the medical record as complete heart block, this condition rarely requires permanent pacemaker implantation.[2] Thus, simply finding the diagnosis "complete heart block" somewhere in the chart, even though it may quite properly have been omitted from the face sheet, is no guarantee that pacemaker implantation was justified. For this reason, our study stated that patients deemed "appropriate" candidates for pacers may have actually been given them without adequate justification.

Similarly, while sick sinus syndrome may be an appropriate justification for a pacemaker, it is also a vague and overused diagnosis. In our study this diagnosis was considered an appropriate diagnosis for pacemaker insertion only because of the limitations of the data base. A study purporting to be a chart review, however, must be more critical. As has been pointed out by Marriott and Cozensky,[3] cardiologists, not to mention less trained physicians, have a marked tendency to overdiagnose atrioventricular block and sick sinus syndrome based on electrocardiograms. Marriott and Cozensky believe, and we concur, that this failing is an important cause of unnecessary pacemaker implantation.[4] Furthermore, the diagnoses "found" in the chart may have been tentative and subsequently discarded by the physician and therefore would not appear on the face sheet. Since the reviews in the Scherlis and Dembo study generally do not appear to have been conducted by cardiologists, much less by experts in cardiac pacing, these factors could not have been considered and the authors cannot properly claim, as they did, to have determined the actual incidence of unnecessary pacemaker implantation.

Scherlis and Dembo also state that 20% of the diagnoses listed on the face sheet were so vague that they were "subject to misinterpretation by the coder." The authors do not state whether these diagnoses actually were misinterpreted. Nor do they determine how often the coder misinterpreted diagnoses in cases we labelled "appropriate."

We have never represented our study as the definitive statement on unnecessary pacemaker implantations. In fact, we have been careful to point out the limitations in our data. While some of Scherlis and Dembo's points are valid, and were acknowledged in our report, we were astonished to learn that in 53% of the charts surveyed, the physician simply failed to include on the summary face sheet a diagnosis that would justify the need for a device and procedure costing more than $7,000.

In a conversation with Scherlis before the completion of his study, we expressed our willingness to facilitate a study that would allow expert and distinterested cardiologists to review the charts of Maryland patients receiving permanent pacemakers. Such a review would include patients from the groups identified as "unnecessary" and "questionable" as well as from the group found "appropriate." Scherlis declined this offer, preferring instead to conduct an independent study for the express purpose of refuting our work. Looked at in this light, his results are not surprising. Consequently, the incidence of unnecessary pacemaker implantation as determined by a proper chart review remains to be determined. To that

end, our offer to cooperate in a thorough study of the issue still stands.

REPLY: The original report by the Health Research Group contained allegations about the unnecessary implantation of permanent pacemakers in Maryland. In describing their methodology which was based on "face sheet" information only, they now state that they "... were aware of its limitations." In their original report, they state that "even with the limitations inherent in our study—limitations which probably resulted in an underestimate of the problem—we believe that we have uncovered a serious problem that wastes millions of Government and private health care dollars every year." Further, they do state that an examination of the medical record "... would likely result in some crossovers from one category to another. But because of our liberal criteria, we believe that more patients would go from "appropriate" or "questionable" to "unnecessary" than from "unnecessary" to either of the other 2 categories." Such preconceptions without subsequent documentation are difficult to accept. The release of their study did not adequately include the limitations which they now emphasize. The Health Research Group's recommendations were based on unconfirmed allegations and should be evaluated on that basis.

We are accused of failing to acknowledge the "... obvious bias inherent in the method" we employed. We had prior experience with such activities as peer review, mortality studies, focused review, utilization review, professional service review organization activities, and quality assurance programs—all of which utilize face sheet data. We have been aware of the shortcomings of this source of information as a determinant of quality of care or appropriateness of procedures. The letter sent to the cooperating hospitals reflected this concern, but the allegations about hospital bias and the resultant inability of individual hospitals to objectively review the medical records because of this letter are unacceptable. Each of the 32 hospitals responded with essential similar data; that is, complete chart review provided the justification for permanent pacemakers which had not been included on the face sheet. As stated in our report, the study was performed as follows. In each hospital, a computer printout of the chart numbers of the medical records to be reviewed was sent to the Quality Assurance Chairman and reviews of the medical record were undertaken by members of the Quality Assurance Committees or, in several instances, members of the Utilization Review Committees, teams of cardiologists, or heads of the Departments of Medicine in their respective hospitals. For each medical record reviewed, the sources of the additional data were provided, that is, consultation notes, operative notes, progress notes, and electrocardiograms. In each hospital, whatever the review mechanism, the reported problems with face sheet data were similar.

With the enormous publicity given the Health Research Group study in the Senate, in the lay press, and on television, blinding of the reviewer about the purpose of the study was impossible. Our study had very straightforward goals: "... to determine the validity of using only face sheet data for the determination of appropriateness of procedures. Additional consideration was given to the general problem of trying to establish guidelines for pacemaker insertion." We used *exactly* the same criteria employed by the Health Research Group for pacemaker insertion and clearly stated this.

In several instances, the indications listed by the Health Research Group are not as rigid as we would have liked were we to have initiated a similar study. We therefore utilized exactly the same criteria as they did but used the entire chart as a source of information and not only the face sheet. Hence, we did not define sick sinus syndrome, complete atrioventricular block, or syncope. We did not review all of the charts of the patients who received permanent pacemakers in Maryland in 1979 and 1980 but only those which fulfilled the Health Research Group criteria of "questionable" or "unnecessary." It may be true that there were errors in charting in that group as well, but a detailed chart review of those characterized as "questionable" or "unnecessary" was given the first priority in view of the allegations by the Health Research Group as related to these 2 categories. We had no "double standard" and clearly stated our methodology. In response to the query about those diagnoses which were so vague that they were "subject to misinterpretation by the coder," these diagnoses actually were misinterpreted and were so classified. Again, we did not review the charts of those patients who were characterized as "appropriate" and therefore cannot state how often the coder misinterpreted diagnoses in these cases. We would not be surprised were there to be errors in those patients as well.

We did ask the reviewers of the medical charts to state whether, after final analysis of the total medical record, they felt that the pacemaker insertions were or were not justified. As we stated in our study, "In a few instances, the hospital reviewers commented that the pacemaker insertion was judged appropriate although the criteria enumerated in the Health Research Report were not present. The authors, however, included all of these cases as being inappropriate for the purpose of this report and in order to make a direct comparison of face sheet data with complete medical record review." There are accepted criteria for pacemaker insertions in addition to those listed in the Health Research Group report and which we discussed in our study. Our primary purpose was to determine the validity of the utilization of face sheet data to determine the appropriateness of permanent pacemaker insertion. We concluded that such face sheet data cannot be used for this purpose.

The authors of the Health Research Group have indeed performed a valuable function for the medical community and for health related groups. Their study served as the basis for our report which demonstrated that face sheet data are unreliable. They are "astonished" that diagnoses which justified procedures costing $7,000 are omitted from the face sheet. We are not since the face sheets have not served as the vehicle for physician reimbursement. This astonishment is only the initial phase of an educational process for them and for many health care providers who are beginning to understand the poor quality of face sheet data. Although their study is flawed by the use of such data, we are indebted to them for providing the impetus to again demonstrate the problems inherent in the analysis of such data.

As to the private conversation referred to, it occurred while our study was already in progress. The cooperation of the Health Research Group was not needed to facilitate our study, which was designed to be a study independent of the original report. Maryland has expert cardiologists, many of whom were involved in this study in their respective hospitals. These hospitals included both medical schools in Maryland as well as 30 additional community hospitals of varying sizes.

The track record of the Health Research Group is not one which encourages cooperation or confidence in its ability to participate in health research where a knowledge of technical terminology, chart problems, or face sheet data is concerned.

AORTOCORONARY BYPASS IN ASYMPTOMATIC OR MILDLY SYMPTOMATIC CORONARY PATIENTS

Since aortocoronary bypass operations first came into use, attempts have been made to evaluate the prognosis of patients with medically treated coronary heart disease (CAD). Although mortality figures are usually presented for 1-, 2-, and 3-vessel CAD, it became apparent that left ventricular function, expressed in terms of ejection fraction, is a more potent discriminator of poor risk patients than are the number of vessels involved by the atherosclerotic process. The most convincing data, based on >20,000 patients (Coronary Artery Surgery Study),[1] showed an annual mortality of patients with 3-vessel disease of 7% and that of the subset with good left ventricular function, 3.6%.

The study by Kent et al[2] addresses the prognosis of 147 medically treated patients with CAD who were asymptomatic or mildly symptomatic. This study generally confirms the good prognosis of patients in this category. However, the authors found a subset of patients with an "extremely grave" prognosis,

namely, those with 3-vessel CAD and poor exercise capacity for whom they recommend bypass surgery without further randomized study. Most patients in this subset showed good ejection fractions.

This conclusion differs from others. The entire series shows a peculiar distribution of fatal cases: With a 4-year follow-up, 7 of the 8 deaths occurred during the first year. Of these, 5 were in the "extremely grave" subset, which involved only *17 patients* (5 deaths and 12 survivors in 1 year). The authors calculated a 9% annual mortality for this subset. This is incorrect: it is roughly a 30% first-year mortality, a figure so striking that it almost certainly indicates a powerful hidden bias in the series or perhaps a freak chance occurrence. A question can be raised whether a population referred to a cardiac center, regardless of reasons for the referral, can ever be considered a random sample.

Asymptomatic patients especially should not be recommended for bypass surgery on the basis of experience with a few cases, but require solid data and convincing evidence. If "poor exercise capacity" is an important discriminating factor (which I doubt), a major investigation of this problem is in order.

Arthur Selzer, MD
San Francisco, California

1. **Mock MB, Ringqvist I, Fisher L, et al.** The survival of nonoperated patients with ischemic heart disease: the CASS experience (abstr). Am J Cardiol 1982;49:1007.
2. **Kent KM, Rosing DR, Ewels CJ, Lipson L, Bonow R, Epstein SE.** Prognosis of asymptomatic or mildly symptomatic patients with coronary artery disease. Am J Cardiol 1982;49:1823–1831.

REPLY: Selzer raises an important issue which we addressed in a recent report; that is, whether a sufficiently high-risk subgroup of patients with 3-vessel disease can be identified so that a coronary bypass operation can seriously be considered. We did identify such a subgroup: those patients with 3-vessel disease and poor exercise capacity. The overall mortality of patients with 3-vessel disease that we observed was remarkably similar to that of the European Cooperative Study, the medical group of the Veterans Administration Study, and the recently published Coronary Artery Surgery Study. The average annual mortality in our series was 6%, whereas that of the Coronary Artery Surgery Study was 7%. Moreover, we identified a lower risk subgroup with an annual mortality of 4% (patients with good exercise capacity), just as the Coronary Artery Surgery Study did (patients with good left ventricular function, an annual mortality of 4%). If a subgroup with an annual mortality less than the mean is found, it necessarily implies that a subgroup with an annual mortality higher than the mean is present. In our study, this was the subgroup with poor exercise capacity, in which the annual mortality was 9%. Annual mortality of this group was calculated by standard life-table techniques and was expressed for the entire observation period. As Selzer notes, the first-year mortality was high; however, if survival data from most natural history studies are examined, there is frequently a larger mortality in the first year after evaluation, followed by a slow decline. This difference is probably due to selection criteria unknown to the investigators or to the referring physician. Nonetheless, the same selection criteria are probably operative when decisions are made regarding referral of patients with chronic stable angina for invasive studies to any center. Although the number of patients within our subgroup was not large, the poor prognosis of these patients, once identified, was clear. Analysis of radionuclide data from these patients confirms that the patients unable to complete 100 W on the bicycle ergometer were also the patients with a decrement of ejection fraction during exercise. Thus, these patients have a larger amount of myocardium at jeopardy, which may provide a physiologic basis for poor exercise capacity and, perhaps, the likelihood of sudden cardiac death.

FACTORS INFLUENCING LEFT VENTRICULAR HYPERTROPHY IN SYSTEMIC HYPERTENSION

The echographic study by Fouad et al[1] showing that a reversal of left ventricular hypertrophy (LVH) can be achieved during methyldopa treatment even in the absence of either significant or proportional pressure reduction supports the view that factors other than arterial pressure may be involved in both the induction and the reversal of LVH. We[2] found a positive correlation between both resting supine and upright plasma norepinephrine levels (by fluorimetry[3]) and ventricular septal (VS) thickness in borderline hypertensive patients (arterial pressure at rest in systole 140 to 150 mm Hg and in diastole 90 to 95 mm Hg). VS thickness was increased in these borderline patients versus age-matched healthy subjects, whereas posterior wall (PW) thickness was normal. In patients with pressure levels constantly >150/95 mm Hg, VS thickness was significantly increased compared with that of healthy subjects and did not correlate with either norepinephrine or arterial pressure; PW thickness, which was increased in both healthy subjects and borderline patients, correlated with mean arterial pressure but not with plasma norepinephrine levels.

From our data, it is tempting to speculate that septal hypertrophy may be consistently sympathetic-induced, representing an early stage of hypertension-induced LVH which afterwards extends to the left PW where it appears to be mainly afterload-induced. Practical implications include whether diuretics or other agents not reducing sympathetic activity or its effects may be appropriate in borderline patients when one goal of therapy is to limit LVH.

3. **Renzini V, Brunori CA, Valori C.** A sensitive and specific fluorimetric method for the determination of noradrenaline and adrenaline in human plasma. Clin Chim Acta 1970;30:587–594.

REPLY: The letter by Corea et al is an interesting and stimulating suggestion regarding the possible role of adrenergic activity in modulating cardiac structural responses to systemic hypertension. This suggestion has been advanced in different modes and with different degrees of evidence since the initial work of Raab.[1–3] Both cardiac hypertrophy and hypertension are multifactorial processes, so that all aspects of hypertensive LVH cannot be explained by 1 factor alone. Rather than conclude from various correlations mentioned that VS and PW thickness respond to entirely different stimuli, it would probably be more physiologic to assume that both arterial pressure and adrenergic factors influence cardiac hypertrophy and its reversal to varying degrees depending on the type of hypertension.[3]

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

From the Preface:

"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner... This text... is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."

Alfred Soffer, MD

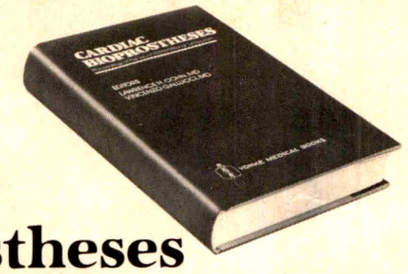
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium
Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT...useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept, Parke-Davis

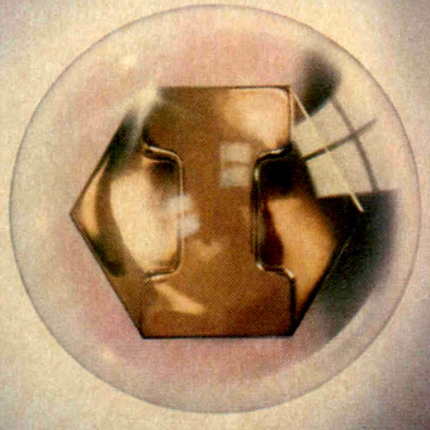
ANGINA PROTECTION AND MORE

INDERAL represents core therapy for angina... unlike calcium antagonists and other beta blockers, only INDERAL is indicated for angina prophylaxis, a wide range of supraventricular arrhythmias and hypertension.

INDERAL, used early, reduces myocardial oxygen demand and protects against ischemia. INDERAL slows heart rate, decreases contractility, and lowers elevated blood pressure. Use INDERAL early in the treatment of angina to prevent ischemia-induced pains and to protect the heart against coexisting arrhythmias...and their consequences.



INDERAL®
(PROPRANOLOL HCl)
COMPREHENSIVE CARDIOVASCULAR PROTECTION

Please see next page for brief summary of prescribing information.

INDERAL®
(PROPRANOLOL HCl)

CORE THERAPY FOR ANGINA.

The appearance of these tablets is a trademark of Ayerst Laboratories.

BRIEF SUMMARY (FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)
Inderal® (propranolol hydrochloride)

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

Propranolol hydrochloride is contraindicated in 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with propranolol; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. Propranolol acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by propranolol's negative inotropic effect. The effects of propranolol and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during propranolol therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, propranolol therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of propranolol therapy. Therefore, when discontinuance of propranolol is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when propranolol is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If propranolol therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute propranolol therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long-term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, propranolol should be withdrawn 48 hours prior to surgery at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since propranolol is a competitive inhibitor of beta-receptor agonists, its effects can be reversed by administration of such agents, e.g., isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), propranolol should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, propranolol may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of propranolol in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine-depleting drugs such as reserpine should be closely observed if propranolol is administered. The added catecholamine-blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of propranolol may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura. *Central Nervous System:* lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics. *Gastrointestinal:* nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis. *Allergic:* pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress. *Respiratory:* bronchospasm. *Hematologic:* agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura. *Miscellaneous:* reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol. *Clinical Laboratory Test Findings:* Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

—Each hexagonal-shaped, orange, scored tablet is embossed with an "I" and imprinted with "INDERAL 10," contains **10 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0421-81) and 1,000 (NDC 0046-0421-91). Also in unit dose package of 100 (NDC 0046-0421-99).
—Each hexagonal-shaped, blue, scored tablet is embossed with an "I" and imprinted with "INDERAL 20," contains **20 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0422-81) and 1,000 (NDC 0046-0422-91). Also in unit dose package of 100 (NDC 0046-0422-99).
—Each hexagonal-shaped, green, scored tablet is embossed with an "I" and imprinted with "INDERAL 40," contains **40 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0424-81) and 1,000 (NDC 0046-0424-91). Also in unit dose package of 100 (NDC 0046-0424-99).
—Each hexagonal-shaped, pink, scored tablet is embossed with an "I" and imprinted with "INDERAL 60," contains **60 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0426-81) and 1,000 (NDC 0046-0426-91). Also in unit dose package of 100 (NDC 0046-0426-99).
—Each hexagonal-shaped, yellow, scored tablet is embossed with an "I" and imprinted with "INDERAL 80," contains **80 mg** propranolol hydrochloride, in bottles of 100 (NDC 0046-0428-81) and 1,000 (NDC 0046-0428-91). Also in unit dose package of 100 (NDC 0046-0428-99).
The appearance of these tablets is a trademark of Ayerst Laboratories.
Store at room temperature (approximately 25° C).

INJECTABLE

—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as 1 ml ampuls in boxes of 10 (NDC 0046-3265-10).
Store at room temperature (approximately 25° C).

QUIK-SILVER.™ A NEW STANDARD FOR RESTING ELECTRODES.

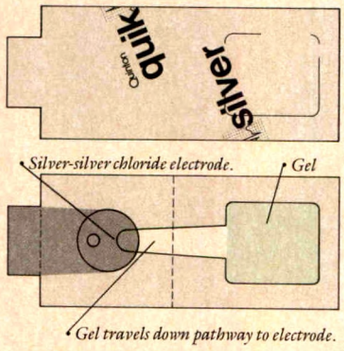
It used to be a tough choice. You could endure the time-consuming mess of reusable electrodes. Or pay the considerable expense of disposable electrodes.

You don't have to make that choice anymore. Because now there's a new standard for resting electrodes: Quik-Silver by Quinton.

A new standard for performance.

The first thing you'll notice about a Quik-Silver electrode is that it doesn't look like an ordinary electrode. That's because it was engineered to be superior.

Quinton started with silver. As the leader in stress test electrodes, we knew the silver-silver chloride electrode offered unparalleled performance. We made a commitment not to sacrifice that performance. The result: Quik-Silver is the first resting electrode ever to offer the benefits of silver-silver chloride. The first to offer superior electrical characteristics. And one of the few to offer defibrillation recovery.



A new standard for convenience.

Quik-Silver makes ECG testing as simple as one, two, three. Its low-profile design incorporates a gel receptacle at one end of a rectangular strip and the silver-silver chloride electrode at the other end. To apply, simply stick it on the patient and squeeze the gel receptacle. Gel travels from the receptacle down a narrow pathway to the electrode. Attach the easy-to-use clip, and you're ready to test. No mess. No hassle. And like the name says, it's fast.

Compare it to traditional reusable electrodes, a Welsh cup, for instance. The Welsh cup is time-consuming, messy and unsanitary. Quik-Silver is sanitary and can be applied in a fraction of the time. And unlike Welsh cups, it is designed to stick to the patient—and stay put.

A new standard for cost-effectiveness.

Superior performance. Unmatched convenience. You'd expect Quik-Silver to be more expensive. Just the opposite. Because of Quinton's state-of-the-art design, Quik-Silver can be produced far more efficiently than standard electrodes. So we can offer it to you for considerably less.

Even the clip is cost efficient. It's designed to adapt to your existing patient cables.

There's a new standard of excellence in resting electrodes. For more information on Quik-Silver, call Quinton at 1-800-426-0347. Or write us at 2121 Terry Avenue, Seattle, WA 98121. Telex 328840. Distributed worldwide.

UNIVERSITY OF MEDICINE LIBRARY

In Cardiac Edema*...

Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Dyazide® is a trademark of SK&F Co.

When You Need to Conserve K+

SK&F CO.
a SmithKline company
Carolina, P.R. 00630

Serum K+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

* **WARNING**

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone; restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, Dyazide should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on Dyazide when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with Dyazide. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. Dyazide interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with Dyazide, but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and Dyazide should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. Dyazide should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on Dyazide, although a causal relationship has not been established.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

CIBA

SLOW-K®
potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

Abbreviations in the AJC

Some editors of medical journals allow abbreviations and others do not. I favor *limited numbers* of *appropriate abbreviations for commonly used terms* in articles submitted to the AJC for 2 reasons: (1) abbreviations save space and, therefore, permit more articles to be published, and (2) abbreviations, if limited to commonly used terms, decrease rather than increase reading time. In general, I prefer to limit abbreviations to 3 per manuscript and to the terms appearing in the manuscript's title.

An upcoming paper in the AJC was entitled "*Left ventricular* response to isometric exercise and its value in predicting the change in ventricular function after *mitral valve replacement* for *mitral regurgitation.*" The phrase "left ventricular" (occupying 16 spaces) appeared 38 times, "mitral regurgitation" (20 spaces) 28 times, and "mitral valve replacement" (24 spaces) 12 times. Spelling out these 3 phrases would have occupied 1,456 spaces, but by abbreviating each (LV, MVR, MR), only 168 spaces were used and 24 single-column lines were saved—an average of nearly 8 column lines per printed page. (Each column in the AJC contains 62 lines and each line, 54 spaces.) Another paper entitled "Relation between the site of origin of *ventricular tachycardia* and relative *left ventricular* myocardial perfusion and wall motion" used the phrase "ventricular tachycardia" (23 spaces) 57 times and the phrase "left ventricular" 42 times. Spelling out these 2 phrases would have occupied 1,983 spaces, but the abbreviations occupied only 198 spaces and 33 single-column lines were saved, an average of >8 column lines per printed page. Another recent paper entitled "Effect of *atrial fibrillation* on atrial blood flow in conscious dogs" used the phrase "atrial fibrillation" (19 spaces) at least 78 times and the single abbreviation "AF" saved 1,326 spaces or >24 lines. Because >40 articles appear now in each regular monthly AJC, averaging 228 text pages per issue, the savings in text pages each month by use of a few abbreviations is enormous, and this saving allows more articles to be published!

Abbreviations must be limited to *commonly recognized terms* (see later). Recently, I reviewed a manuscript which used the abbreviation "LVT," indicating "left ventricular thrombus." "LVT" is not a commonly recognized abbreviation and therefore I changed it to "LV thrombus," abbreviating "left ventricular" throughout but not "thrombus." Incidentally, the most commonly used phrase in cardiologic journals is "left ventricular"; hence, the abbreviation "LV" is highly useful. It should be noted that "LV" most commonly signifies "left ventricular," not "left ventricle," which is far less commonly used.

Not only must abbreviations be limited and of commonly used terms, but they must be *appropriate* in that *each letter of the abbreviation must stand for a single word.* It is inappropriate to use a letter for 1 word in a phrase, then use >1 letter for a second word in the same phrase. Specifically, it is inappropriate to abbreviate "hypertrophic cardiomyopathy" as "HCM"—this abbreviation breaks the rule of parallelism—1 letter stands for 1 word and a separate letter stands for each of 2 major syllables in the second word. The proper abbreviation is "HC." The commonly used abbreviations for the coronary arteries, namely, "RCA," "LAD," and "LCx" are not consistent. If "CA," the abbreviation for "coronary artery," is used after the "right" to read "RCA," then it should be used after the "left anterior descending" to read "LADCA" and after the "left circumflex" to read "LCCA." It is inappropriate to abbreviate 2 syllables in "circumflex" and not follow the same principle for the "anterior descending." It is best to abbreviate "left anterior descending" as "LAD" and "left circumflex" as "LC" (omitting the "x"), but not to abbreviate the "right coronary artery"; simply let it be known as "right."

Occasionally, it is warranted to make exception to the

Continued on page A10

abbreviation principle of 1 letter per word. The commonly used abbreviations for "electrocardiogram" (ECG), "atrioventricular" (AV), and "radionuclide angiography or angiocardiography" (RNA) are really inappropriate, but each is so ingrained that they have become appropriate. To abbreviate "electrocardiogram" as "E" or "atrioventricular" as "A" or "radionuclide angiography" as "RA" is confusing. An abbreviation for "echocardiogram" or "echocardiography" is another exception; probably "echo" is the most appropriate abbreviation for either word.

It is best to use certain terms universally to prevent confusion when abbreviating. The term "mitral regurgitation" is better than the term "mitral insufficiency" for several reasons; one is that it allows the abbreviation "MR," which prevents its confusion with "MI," which best stands for "myocardial infarction" or "infarct." Although obviously it would be consistent with the rule of parallelism to abbreviate "coronary heart disease" as "CHD," this might produce confusion with "congenital heart disease" and, therefore, it is preferable to allow "CAD" to signify both "coronary heart disease" and "coronary artery disease." To use the terms "*inter*atrial septal defect" and "*inter*ventricular septal defect" is undesirable because each implies that *extra*atrial or *extra*ventricular septal defects also exist. The prefix "inter" should be discarded. Of course, only 1 atrial septum and only 1 ventricular septum exist. Therefore, the proper terms are "atrial septal defect" (ASD) and "ventricular septal defect" (VSD), not "IASD" and "IVSD." On echocardiograms, the ventricular septum should be labeled "VS," not "IVS."

Finally, once initiated it is important to use abbreviations consistently throughout each page of a paper. When first appearing in both summary and introduction, the phrase to be abbreviated should be spelled out and thereafter abbreviated elsewhere in the manuscript.

Although abbreviations save enormous space, their use results in more time expended by authors, editors, and copy editors to ensure uniformity and appropriateness. It would save all 3 much time and effort if abbreviations were not allowed; but in our era of enormous expense for each published page and limited time to read each page, it is only proper that limited numbers of appropriately used abbreviations be permitted in manuscripts.

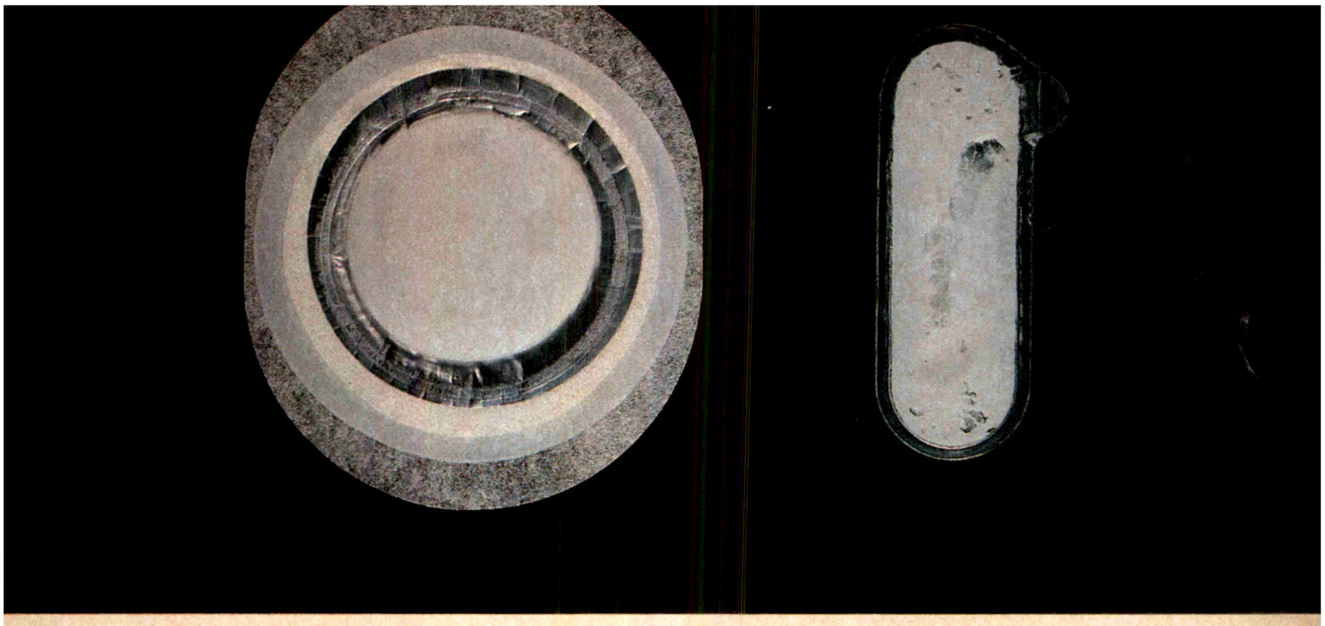
Some of the most commonly used standard cardiologic abbreviations are listed at right.

TERMS COMMONLY ABBREVIATED

AF	= atrial fibrillation
AR	= aortic regurgitation
AS	= aortic stenosis
ASD	= atrial septal defect
AV	= atrioventricular
AVR	= aortic valve replacement
BBB	= bundle branch block
BP	= blood pressure
CABG	= coronary artery bypass grafting
CAD	= coronary heart disease
CHF	= congestive heart failure
Coronary arteries:	
LAD	= left anterior descending
LC	= left circumflex
LM	= left main
ECG	= electrocardiogram
echo	= echocardiogram or echocardiography
EF	= ejection fraction
HC	= hypertrophic cardiomyopathy
LV	= left ventricular
MI	= myocardial infarct or infarction
MR	= mitral regurgitation
MS	= mitral stenosis
MVP	= mitral valve prolapse
MVR	= mitral valve replacement
PA	= pulmonary artery
PDA	= patent ductus arteriosus
RNA	= radionuclide angiocardiography
RV	= right ventricular
TF	= tetralogy of Fallot
TGA	= complete transposition of the great arteries
TR	= tricuspid regurgitation
VF	= ventricular fibrillation
VPC	= ventricular premature complexes
VSD	= ventricular septal defect
VT	= ventricular tachycardia
WPW	= Wolff-Parkinson-White syndrome

William C. Roberts

William C. Roberts, MD
Editor-in-Chief



One costs 13% less.

Nitro-Dur: a significant savings for the angina patient.

When a patient takes a medication every day and possibly for the rest of his life, cost becomes a significant factor.

Nitro-Dur is the most economical transdermal nitroglycerin: the 10 cm^2 size costs 11% less and the 20 cm^2 size costs 13% less than the comparable products from Ciba. In one year, patients using Nitro-Dur can save up to $75 compared to patients using the Ciba product.[1]

Nitro-Dur patients save in another way. The larger adhesive surface of Nitro-Dur means that there is less chance of adhesive failure, thus saving the patient the cost of replacement.

Reduced patient cost. One more reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[2] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

CLASSIFIED

ACADEMIC CARDIOLOGIST

Director of Nuclear Cardiology is sought for an expanding program in a large teaching hospital on Long Island, New York. This position is geographic, full-time, and the compensation is attractive. Applicant should be Board Certified in Internal Medicine and in Cardiovascular Diseases. Qualifications for the academic rank of Associate Professor or higher is desirable. Outstanding, enthusiastic teacher/clinician with proven administrative and research ability is sought. Send CV in confidence to Steven M. Zeldis, M.D., Acting Chief of Cardiology, Nassau Hospital, 259 First Street, Mineola, L.I., New York 11501.

FOR SALE

Ekoline 20A M-Mode echocardiographic unit. Contact GREG WALKER, Good Samaritan Hospital, West Palm Beach, Fla., 305-655-5511.

Northeastern Pennsylvania—Dynamic practice opportunity in cardiology available. Modern JCAH approved, 160 bed general acute care hospital forty-five minutes northwest of Allentown, Pennsylvania, provides outstanding potential and opportunity in excellent geographic location for building specialty practice. Please send resume to Tod Mammuth, NEEMA Medical Services, Inc. 399 Market Street, Philadelphia, PA 19106 or call 800-523-0776 (outside PA) or 215-925-3511 (in PA).

CARDIOLOGIST position available at the modern, multispeciality, Veterans Administration Outpatient Clinic in Sacramento, California, fully affiliated to U.C. Davis. ABIM and BC or BE in Cardiology required. Academic appointment level dependent on qualifications. Equal Opportunity Employer. Application period will close May 31, 1983. For information contact Eugen O. Grecu, M.D., Chief Medical Officer, V.A. Outpatient Clinic, 4600 Broadway, Sacramento, CA 95820 (Telephone number 916-440-2633).

Dialog of the Hearts –by Hemingway:

"And she smiled and from no distance said, 'Hello, my Inglés.'

'I'm not an Inglés', he said very lazily.

'Oh yes, you are', she said. 'You're my Inglés', and reached and took hold of both his ears and kissed him on the forehead.

'There', she said. 'How is that? Do I kiss thee better?'

Then they were walking along the stream together and he said, 'Maria, I love thee and thou art so lovely and so wonderful and so beautiful and it does such things to me to be with thee that I feel as though I wanted to die when I am loving thee'.

'Oh', she said. 'I die each time. Do you not die?'

'No. Almost. But did thee feel the earth move?'

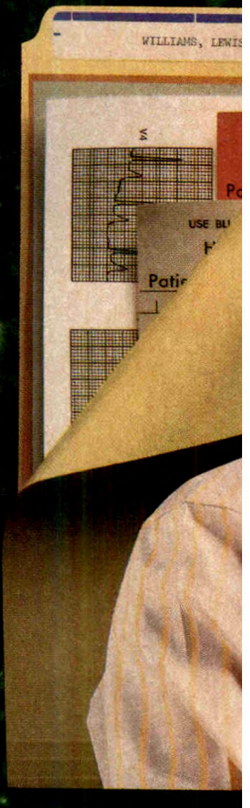
'Yes. As I died. Put thy arm around me, please'.

'No. I have thy hand. Thy hand is enough".

The Dialogue of Robert Jordan and Maria from "For Whom the Bell Tolls".

Another Dialog soon to appear—by Siemens.

LOOKING BENEATH THE SURFACE...



may reveal the cause of his hypertension...

In their study of the humoral mechanisms involved in hypertension, researchers are focusing not only on the kidneys and adrenal glands but on other glandular bodies as well.

Recently, a new aldosterone-stimulating factor (ASF) has been isolated from normal human urine.* Through immunofluorescence, ASF—a glycoprotein with a number of similarities to ACTH and angiotensin II—has been traced to the pituitary gland. By helping to raise plasma levels of aldosterone, which in turn leads to increased renal sodium retention, ASF presumably contributes to hypertension. The importance of its role must still be determined—and eventually will be, as researchers continue to look "beneath the surface."

*Sen S *et al: Hypertension 3*(Suppl 1):81-86, May-Jun 1981. By permission of the American Heart Association, Inc.

as well as the cause of his excessive anxiety

When the hypertensive patient also has anxiety which may cause him to resist, or even ignore, his medical regimen, discreet probing often provides sufficient information about possible underlying causes to help you deal with the situation. At times, however, neither counseling nor reassurance seems to work. The patient remains tense, apprehensive and—perhaps most damaging of all—noncompliant.

In such cases, adjunctive Valium (diazepam/Roche) can be distinctly helpful. Valium works promptly and dependably to relieve the excessive anxiety that patients may have because of their concern over their organic illnesses. Typically, initial calming occurs within hours—more sustained, decisive relief of anxiety symptoms in just a few days. With his intense anxiety under control, the hypertensive patient may be better able to cope with his problems and to tolerate the demands of his treatment program.

Another important advantage: Valium has been used with most primary cardiac medications, including cardiac glycosides, diuretics and vasodilators. Side effects more serious than drowsiness, fatigue and ataxia are rare and seldom severe. Patients should, of course, be cautioned against drinking alcoholic beverages or driving while taking Valium. Periodic reassessment of the need for psychotropic medication is also recommended.

VALIUM® (IV)

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

A primary choice for anxiety associated with hypertension

Please see summary of product information on the next page.

ROCHE®

VALIUM® (IV)
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
How Supplied: For oral administration, Valium scored tablets—2 mg, white; 5 mg, yellow; 10 mg, blue—bottles of 100* and 500;* Prescription Paks of 50, available in trays of 10.* Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25,† and in boxes containing 10 strips of 10.†

Sequicor® II
DDD (AAI + VAT∆ + VVI)
Unipolar, Multiprogrammable
Cardiac Pacer
SN 233F- 6232
cordis®
Miami, FL, U.S.A.

Introducing

Cordis Sequicor® II

The Second-Generation Automatic DDD Pacer with Telemetry.

Simplified patient management
through uncomplicated programming and pacer function.

Enhanced pacer longevity (10 years)*
resulting from improved circuit efficiency.

Protection from retrograde conduction
by independently programmable atrial refractory periods.

cordis®

Cordis Corporation, Post Office Box 525700, Miami, Florida 33152-5700, U.S.A. Tel. 800-327-2490

*Predicted theoretical service life of 10 years based on 100% dual-chamber demand (DDD) pacing at 70 ppm and delivering 0.6 ms/6 mA pulse into a 510-ohm load.

Cordis Sequicor II Technical Information

The nominal parameter values of the Sequicor II, Model 233F

Modes	DDD, DVI, DAD, VDD, VAT, VVI, DOO, VOO		
Programmed pacing rate, ppm	30 to 120 in 5-ppm increments		
Sensitivity mV (each channel)	Off, 0.5, 1.3, 2.5		
Pulse duration/ output current, ms/mA (each channel)	0.2/2 0.3/3 0.4/4	0.5/5 0.6/6 0.8/8	1.0/10 2.0/12
A-V delay, ms	75, 100, 125, 150, 175, 200, 250		
Refractory, ms (each channel)	250, 300, 350, 400, 500		
Output voltage, V (open circuit)	8 mA or higher below 8 mA	8.4 4.0	
Pace limit, ppm	160		
Battery test rates, magnet applied, ppm	70 62½ 52½	Battery satisfactory Battery nearing depletion Backup pacing (VOO) activated	
Pacing configuration	Unipolar		
Parameters revealed through telemetry	Mode, rate, sensitivity, output current, pulse duration, refractory period, and last two digits of pacer serial number.		

Specifications

Power source	Two Cordis lithium cells
Specific gravity	1.8
Weight, g	73
Thickness, mm	15
Width, mm	57
Height, mm	69
Radiopaque I.D. letters	HK

Important Information—Sequicor II

Indications and Contraindications
The medical literature describes currently accepted indications and contraindications for various pacing/sensing modes. The physician's clinical experience and judgment must ultimately be the guide in selecting the pacing mode best suited to the patient's needs.

Pacing of the ventricles (VVI) is indicated for control of heart rate in patients with A-V block or sick sinus syndrome. *Asynchronous pacing may be contraindicated for long-term pacing when inherent activity is present or is likely to be present in the chamber being paced.* There are no other known contraindications for ventricular pacing to control heart rate.

Atrial-synchronized ventricular pacing (VVD) is indicated for permanent or intermittent complete heart block with normal atrial rhythm. A-V sequential (DVI) pacing is indicated for permanent sinus bradycardia with or without heart block. Automatic dual-chamber demand pacing (DDD) is indicated when there is an A-V conduction disturbance and/or sinus node dysfunction (sinus bradycardia with A-V block or bradytachy syndrome). These atrial pacing modes are intended for patients who would benefit from the restoration of atrial contribution to cardiac output.

Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated for use in the presence of persistent atrial flutter or atrial fibrillation.

Precautions
Use Only Models 255A and 256A Cordis Programmers
Only a Cordis Model 255A Programmer III or Cordis Model 256A Interactive Programmer can be used with the Cordis Model 233F Sequicor pacer. The Sequicor II pacer *will not respond* to programming transmissions from other programmers. Do not use Cordis Models 166 and 222 Omnicor Programmers or programmers of other manufacturers.

"Use Before" Date
To assure maximum service life, pacers must be implanted before the "Use before" date shown on the package label.

Warnings
None.

Adverse Effects
A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer—battery depletion, electromagnetic interference, component malfunction.

Lead—unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient—reaction, infection/erosion, increase in stimulation threshold, hemothorax, pneumothorax, embolism, thrombosis.

Read the *Instructions for Use* for more complete information prior to using.

Caution: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

William C. Roberts, M.D.
Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.

Dean T. Mason, M.D.
Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California

Mary Allen Engle, M.D.
Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York

Lawrence H. Cohn, M.D.
Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

SPECIAL DISCOUNT OFFER

Place a standing order to receive each edition of CARDIOLOGY: 1982 on 30 day approval and receive a 10% discount on this and all future editions.

☐ **YES,** please enter my standing order for CARDIOLOGY: 1982. I understand that each edition (published once a year) will be automatically shipped to me on 30 day approval, and I will receive a 10% discount on this and all future editions. (1982 edition discount price $40.50)

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCD3

Kind-hearted coffee

Cardiac conditions may seem formidable to some patients, especially when diet modifications eliminate favorite foods and beverages. But there's one beverage these patients won't have to give up: coffee.

Sanka® Brand Decaffeinated Coffee is 100% real coffee and it is 97% caffeine-free. Each cup of Sanka® contains just a fraction of the caffeine found in an equivalent cup of regular coffee. That's why it will not exacerbate underlying cardiac or hypertensive conditions in patients who are bothered by too much caffeine.

And because Sanka® tastes good, it aids patient compliance. What's more, it is available everywhere in instant, freeze-dried or ground roast forms. It can even be found at restaurants in convenient single-service packages.

Non-stimulating Sanka® is ideally suited to many special diets. And physicians recommend it more than all other brands of decaffeinated coffee combined.

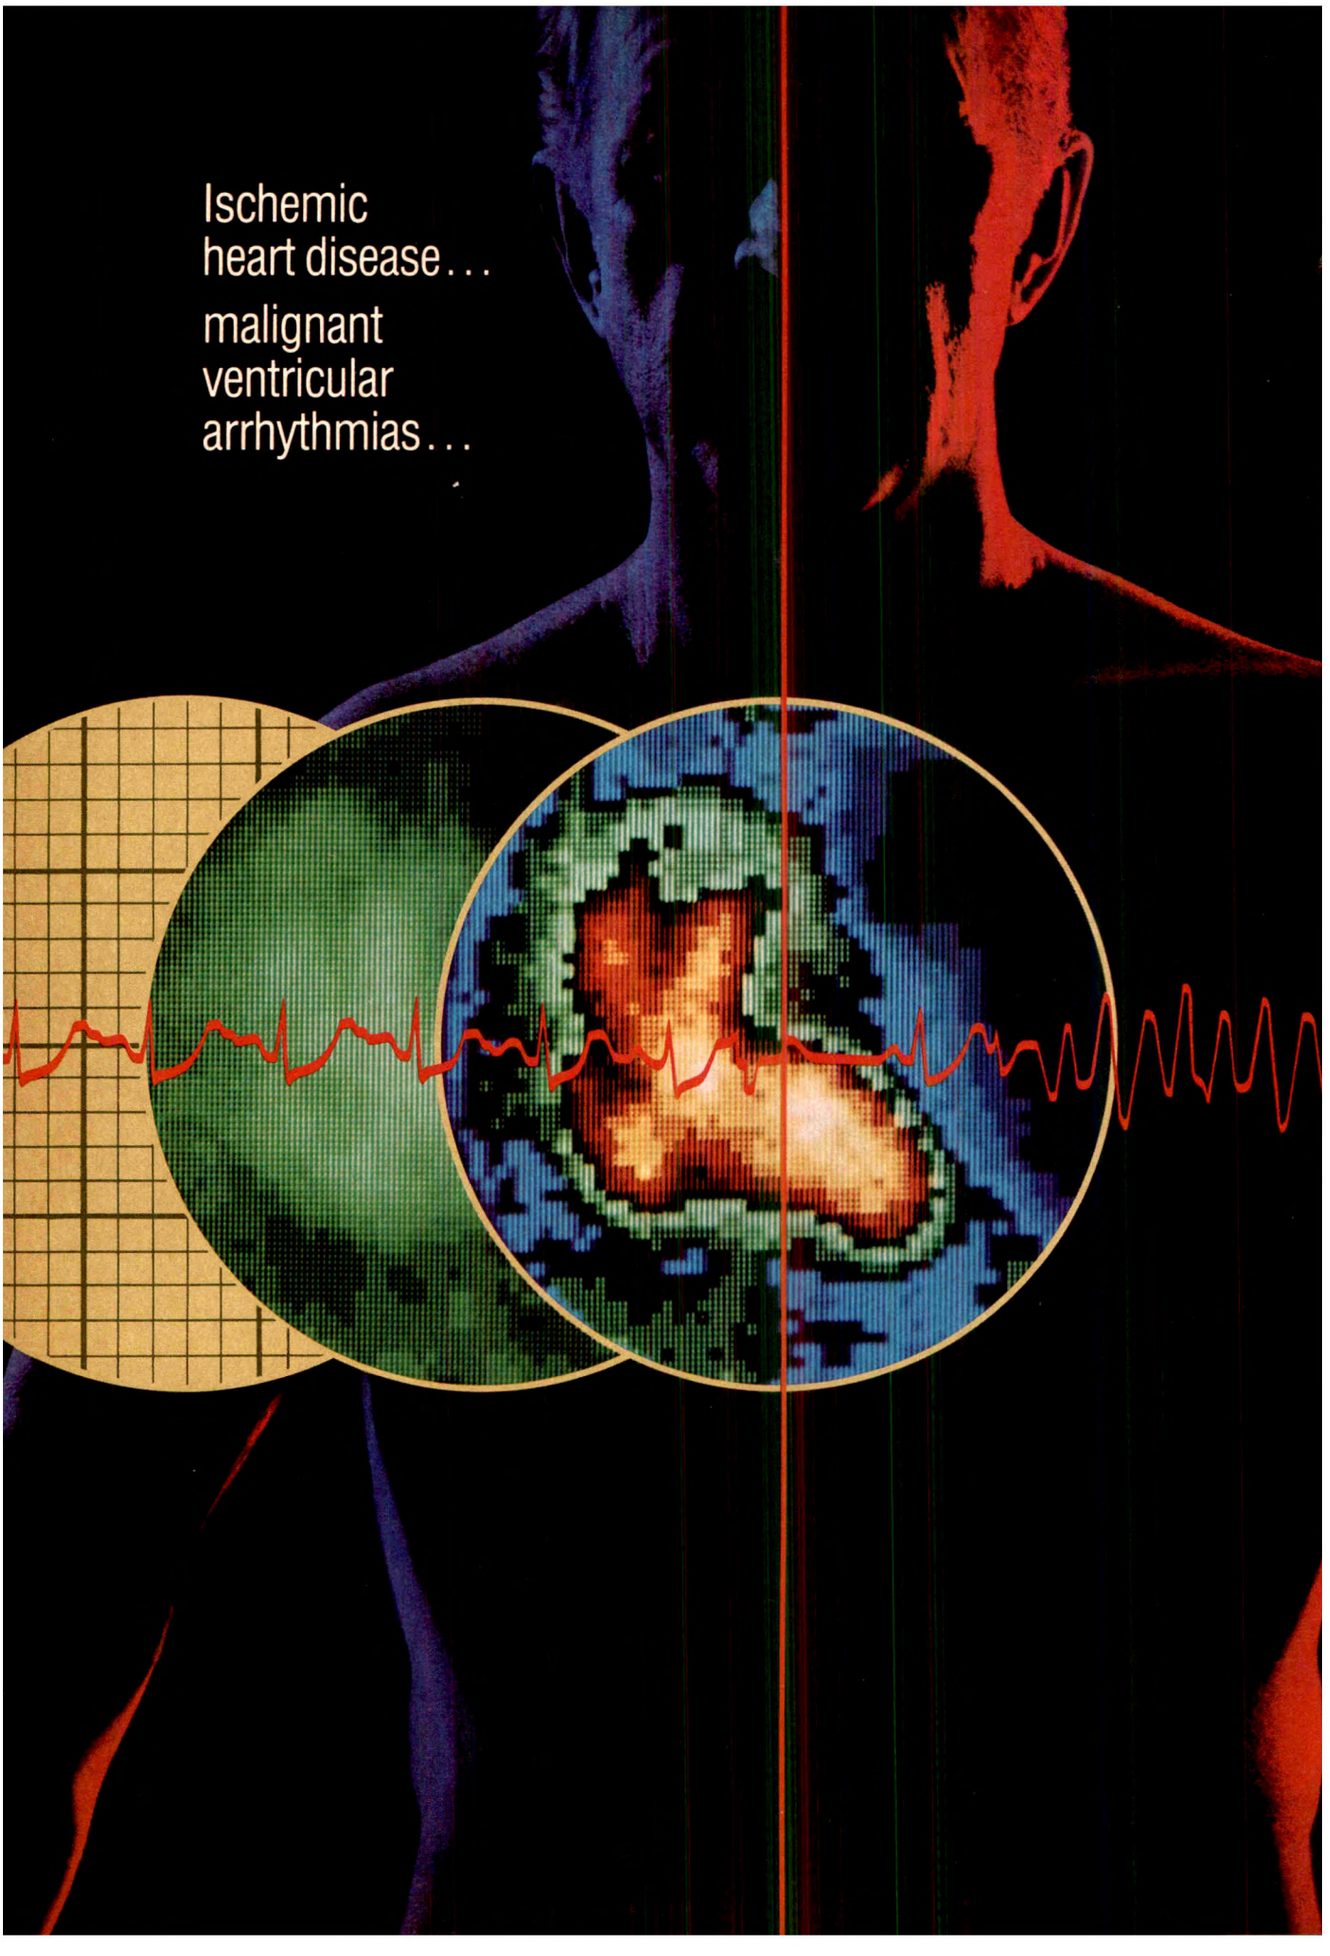
COLLEGE OF MEDICINE LIBRARY



Ischemic
heart disease...
malignant
ventricular
arrhythmias...

ZEROING IN ON THE CANDIDATE AT RISK

Frequent and complex forms of PVCs sharply increase the risk of sudden cardiac death (SCD) in patients with ischemic heart disease, especially in the presence of left ventricular dysfunction.[1,2]

To reduce the risk of potentially fatal arrhythmias in such patients

QUINAGLUTE® 324 mg DURA-TABS®

(quinidine gluconate)

- If initially tolerated, can usually be taken successfully over long periods.[3]
- Demonstrated by programmed ventricular stimulation to be effective in accepted "standard" doses.[4]
- BID or TID dosage helps improve compliance while providing 24-hour antiarrhythmic activity.
- "As a rule, GI toxicity associated with quinidine gluconate is less frequent and less severe than that associated with quinidine sulfate."[5]

QUINAGLUTE® (quinidine gluconate) DURA-TABS®

INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:

1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).

2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).

CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.

WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine.

2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered.

3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring.

4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals.

5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity.

7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal.

8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.

PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.

Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.

Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.

Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.

Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.

ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.

Less frequently encountered adverse reactions:

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.

See package insert for full information.

CORONARY HEART DISEASE

1045 Late Prognostic Value of Scintigraphic Parameters of Acute Myocardial Infarction Size in Complicated Myocardial Infarction Without Heart Failure

ELIAS H. BOTVINICK, JUAN F. PEREZ-GONZALEZ, RICHARD DUNN, THOMAS PORTS, KANU CHATTERJEE, and WILLIAM PARMLEY

Scintigraphic quantitation of infarction, perfusion abnormality, and left ventricular function in 25 patients with acute myocardial infarction but without heart failure demonstrated advanced electrocardiographic rhythm and conduction abnormalities. Acute scintigraphic findings were related to the late clinical follow-up performed an average of 14.4 months later. Scintigraphic measures of the extent of infarction and related perfusion differentiated patients who died on follow-up (n = 8) from survivors (n = 17). Only measures of perfusion abnormalities differentiated symptomatic survivors (n = 9) from those who remained asymptomatic (n = 8). The study indicates that the late course of patients with serious rhythm and conduction disturbances but without heart failure during infarction is valuable. Early scintigraphic measurements of infarction and perfusion but not function appear to differentiate among widely differing prognostic groups. Patient prognosis seems related to the extent of acute myocardial damage, reversible or irreversible, which can best be made by noninvasive scintigraphic evaluation.

1052 Differentiation Between Right and Circumflex Coronary Artery Disease on Thallium Myocardial Perfusion Scanning

HENRY N. NEWMAN, RICHARD F. DUNN, PHILLIP J. HARRIS, GEORGE J. BAUTOVICH, ANDREW F. McLAUGHLIN, and DAVID T. KELLY

Thallium defects in the inferior and lateral walls of the heart were correlated with right and circumflex coronary artery disease in 405 patients who underwent coronary arteriography. Inferior wall defects were associated with right coronary artery disease, whereas lateral wall defects were associated with left circumflex disease. Disease in both right and circumflex coronary arteries was best identified by a combination of inferior and lateral defects. Disease in only 1 of these 2 vessels was best identified by a combination of inferior without lateral defects for the right coronary artery and lateral without inferior defects for circumflex disease. The pattern of defects on thallium scanning identified significant disease in the right coronary artery, the circumflex coronary artery, and both.

1057 Left Ventricular End-Systolic Pressure-Volume Relation. A Combined Radionuclide and Hemodynamic Study

ABDULMASSIH S. ISKANDRIAN, A-HAMID HAKKI, CHARLES E. BEMIS, SALLY A. KANE, BARBARA BOSTON, and ANGELO AMENTA

This study examines the effect of increasing heart rate by atrial pacing on the left ventricular pressure-volume relation using combined radionuclide and hemodynamic measurements. The results indicate that atrial pacing has a positive inotropic effect in normal subjects and that abnormal changes in end-systolic pressure/end-systolic volume in coronary artery disease are more common than changes in ejection fraction with atrial pacing.

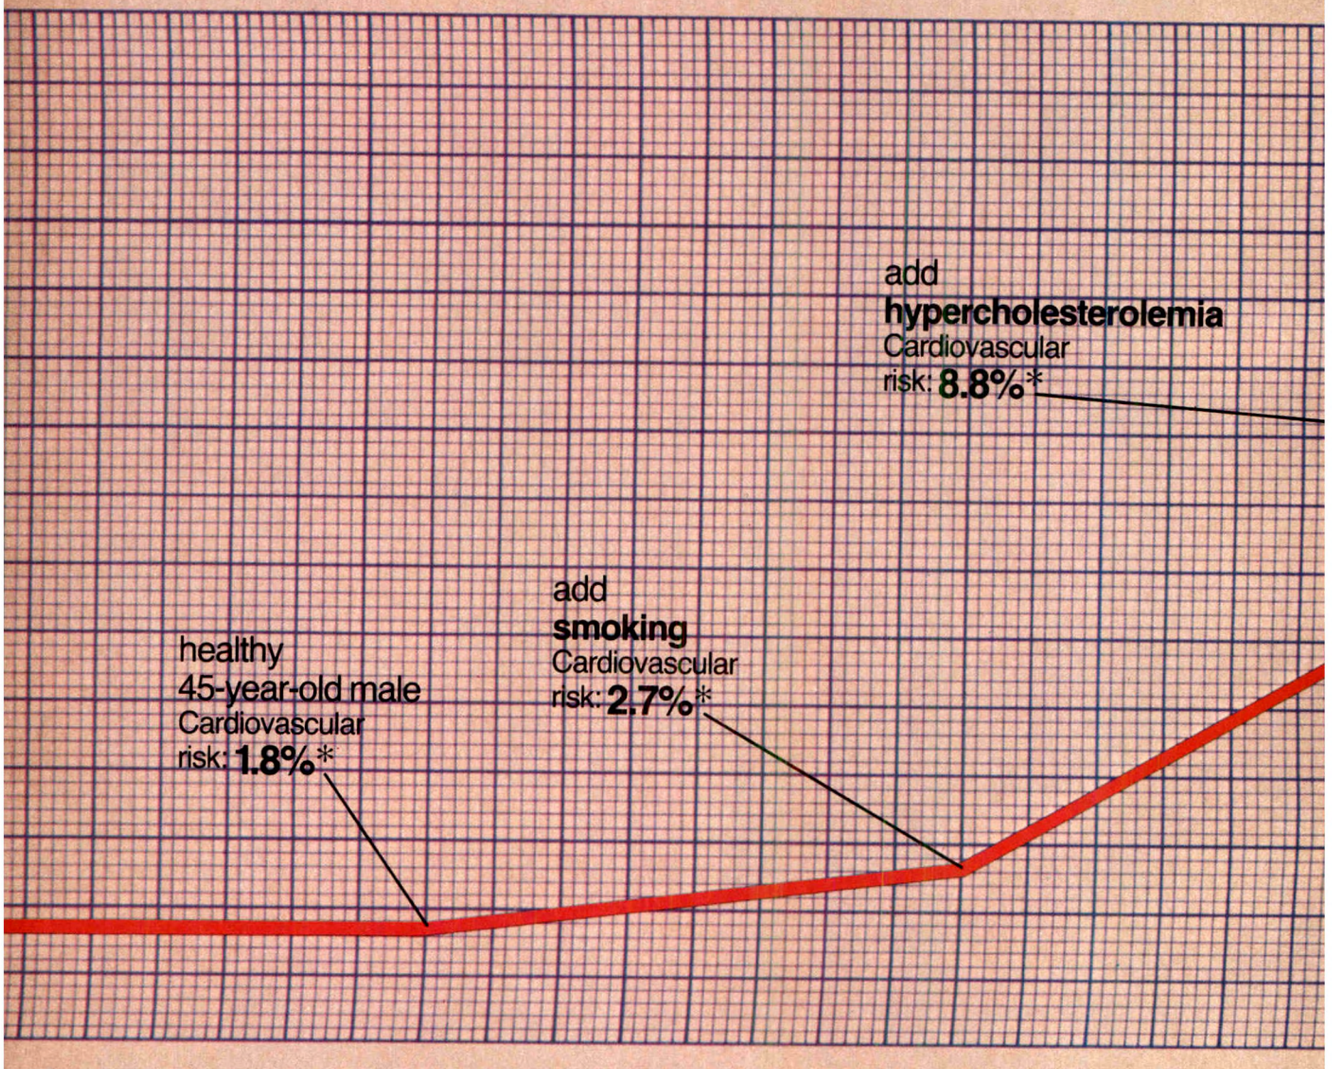
1062 Comparison of Slow-Release Pindolol, Standard Pindolol, and Propranolol in Angina Pectoris

JOHN O. PARKER

Twenty-two patients with stable, exercise-induced angina pectoris who were propranolol responders were assessed over a period of 12 weeks during therapy with standard propranolol, 40 mg 4 times daily, slow-release pindolol, 20 mg once daily, and standard pindolol, 10 mg twice daily. Patients maintained diaries of anginal frequency and nitroglycerin consumption and underwent treadmill exercise testing every 2 weeks before the morning medication. There were no significant differences in nitroglycerin consumption or anginal frequency during the 3 treatment programs. The resting heart rates were higher during therapy with pindolol than with propranolol, but no differences were seen between standard and slow-release pindolol. Treadmill walking time to the endpoint of moderate angina, exercise systolic and diastolic blood pressures, and exercise heart rate were similar

Continued on Page A32

In hypertensive patients

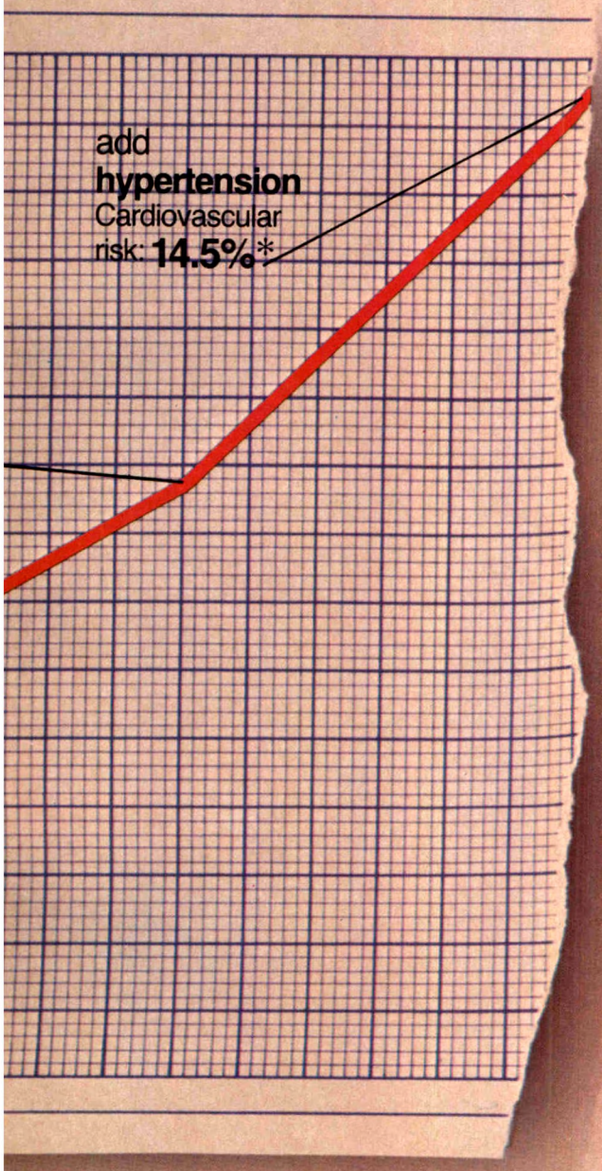


Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing coronary heart disease within 6 years.

Adapted from *Coronary Risk Handbook:* Estimating risk of coronary heart disease in daily practice. 1973, American Heart Assoc., Inc.

Consider the Risks



▪ When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

▪ Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

▪ Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

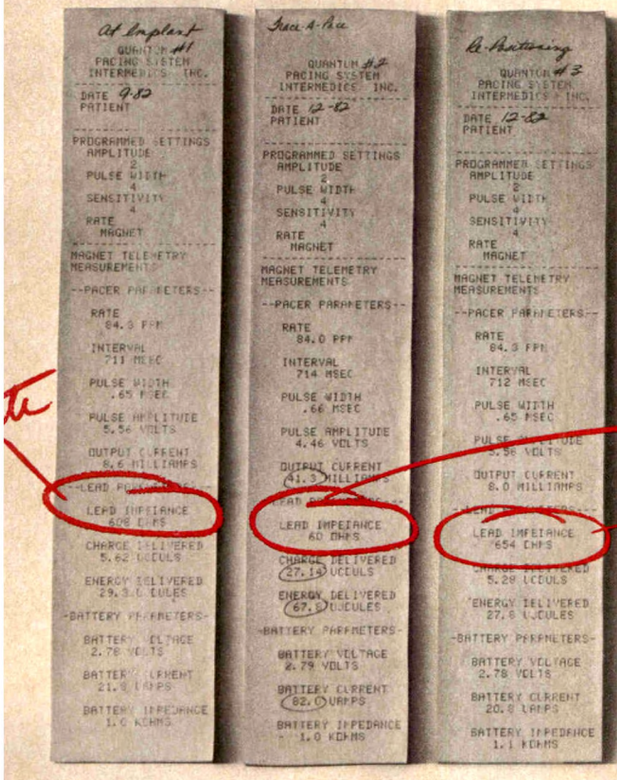
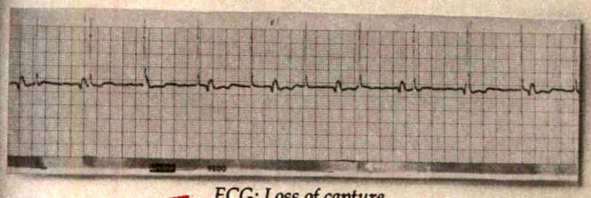
Indication For Pacing: Intermittent Heartblock, Sinus Arrest.

#2 IN A SERIES: QUANTUM—THE PROBLEM SOLVER





ECG: Loss of capture

This is the second in a series of case histories demonstrating the Quantum system's unique ability to help physicians diagnose the condition of a pacemaker patient.

An Actual Case History*

Patient: MALE
Age: 67 YEARS
Indication for Pacing: INTERMITTENT HEARTBLOCK, SINUS ARREST

The patient received a bipolar Quantum™ pulse generator with a transvenous bipolar lead. Intraoperative fluoroscopy and postoperative telemetry indicated satisfactory lead position.

Several months later, during routine telephone follow-up through Intermedics' Trace-A-Pace™ service, the patient's transtelephonic telemetry readout displayed abnormally low lead impedance values. A subsequent ECG strip indicated intermittent pacing, although the patient had experienced no discomfort.

Reexamination revealed insulation fractures of the lead that probably were causing intermittent shorting of the electrode. Access to the lead was gained via the pacer pocket and the repair was effected by medical adhesive and a suture sleeve tied in place. Postrepair pacing is normal with telemetry indicating acceptable lead impedance values.

This is just one example of how Quantum helped pinpoint the exact source of a patient's problem. The complete Quantum pacing system, including a Decoder, Printer, Transmitter, Intermedics Programmer and three pacemaker models, represents the most sophisticated technology available today. By providing you with more information, Quantum helps you better manage your pacemaker patients.

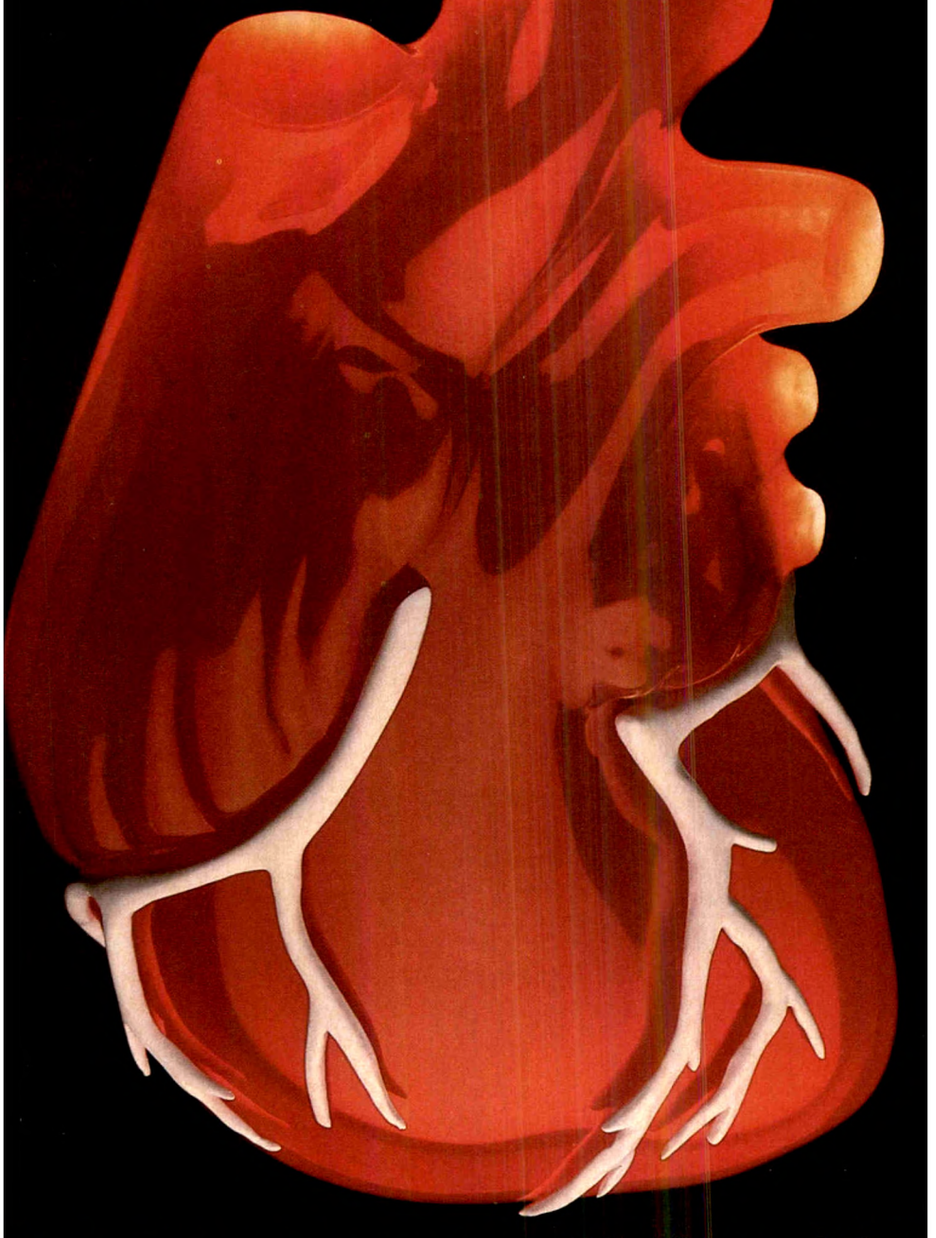
in cardiovascular therapy

New CARDIZEM™ (diltiazem HCl)

ALCIUM CHANNEL BLOCKADI

from Marion Laboratories



Potent coronary vasodilation with a distinctive hemodynamic profile

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

© 1983, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]

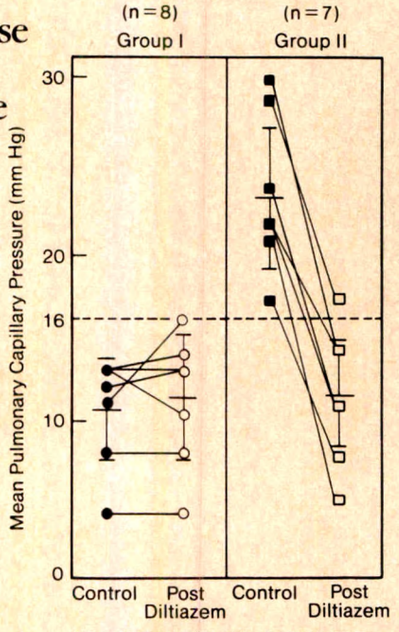
While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.



CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

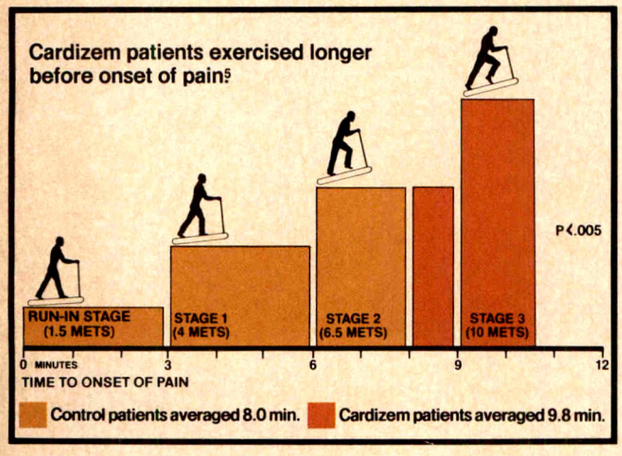
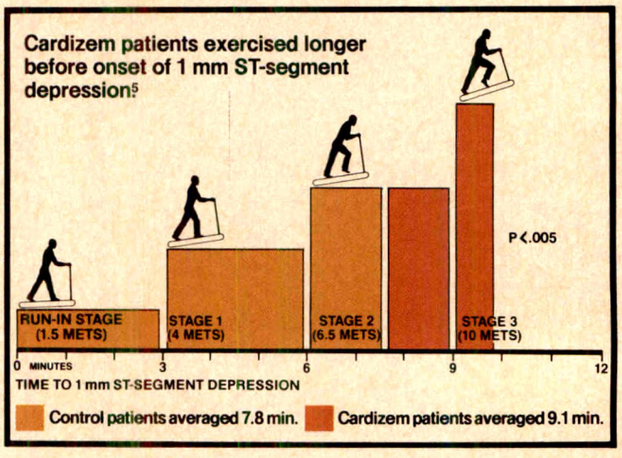
EXCELLENT CLINICAL REPORT TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:
A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

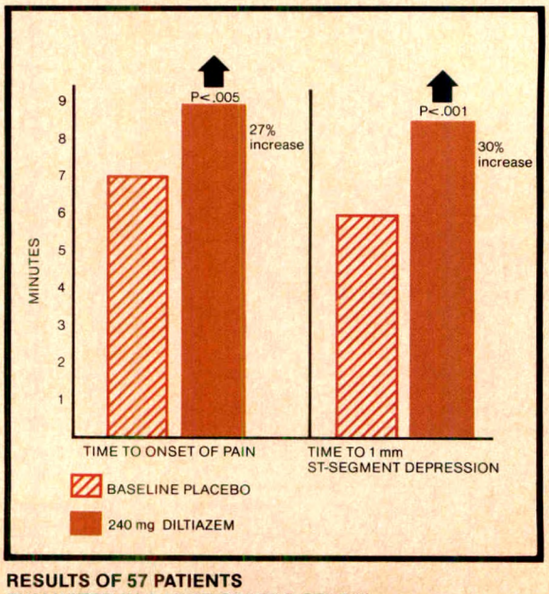
5. Pool PE, Seagren SC, Bonanno JA, et al: The treatment of exercise-inducible chronic stable angina with diltiazem: Effect on treadmill exercise. *Chest* 78(July suppl): 234-238, 1980.

6. Hossack KF, Pool PE, Steele P, et al: Efficacy of diltiazem in angina on effort: A multicenter trial. *Am J Cardiol* 49:567-572, 1982.

*This study is a report from one center in a multicenter study.

CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

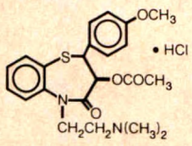
In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

1087 Comparative Functional and Physiologic Status of Active and Dropout Coronary Bypass Patients of a Rehabilitation Program

THAD F. WAITES, EDWARD W. WATT, and GERALD F. FLETCHER

To assess the benefits of regular participation in a medically supervised cardiac rehabilitation program, 22 patients who had undergone coronary artery bypass (2 groups of 11 each) were studied retrospectively. Group I (mean age 53 years) was currently enrolled in the rehabilitation program. Group II (mean age 56 years) had begun but had discontinued the program. The stated reasons for discontinuation were not medical. There was no difference in entry exercise tests, and presurgical catheterization data in both groups were comparable. Mean peak oxygen consumption (VO_2) by modifed Douglas bag technique, heart rate × systolic blood pressure product, and treadmill duration time were recorded in a single testing period. Results revealed that Group I had higher peak VO_2 (30 ml/kg/min) than Group II (24) ($p < 0.005$) and greater treadmill time (11 minutes) than Group II (8) ($p < 0.01$). Nine of 11 subjects in Group I were fully employed, versus 4 of 11 in Group II ($p < 0.01$). One of 11 subjects in Group I had been rehospitalized, versus 5 in Group II. None in Group I but 4 of 11 subjects in Group II smoked. Thus, based on the sampling and methodology of this study, it is concluded that coronary artery bypass patients in rehabilitation programs have greater peak VO_2 and treadmill test time, smoke less, are less often rehospitalized, and are more often fully employed than those who are not in such programs.

1091 Exercise Versus Cold Temperature Stimulation During Radionuclide Cineangiography: Diagnostic Accuracy in Coronary Artery Disease

LAWRENCE J. JORDAN, JEFFREY S. BORER, MICHAEL ZULLO, DAVID HAYES, SPENCER KUBO, JEFFREY W. MOSES, and JOHN CARTER

To assess the relative efficacy of cold temperature stimulation and bicycle exercise in inducing ischemia detectable by radionuclide cineangiography, both stresses were used to study 20 normal subjects and 54 patients with coronary artery disease, 42 of whom had not had myocardial infarction. Regional left ventricular dysfunction was induced by cold in 24 of 41 patients without previous infarction (57%) and by exercise in 34 of 42 patients (81%) ($p < 0.05$), but was absent in all normal subjects during either stress. Using left ventricular ejection fraction as the index of ischemia, sensitivity and specificity of radionuclide cineangiography were assessed over a wide range of ejection fraction changes independently for each stress. During exercise, at ejection fraction changes in which specificity was high, sensitivity also was high, but during cold stress, specificity was relatively poor at ejection fraction changes in which sensitivity was high, and sensitivity was relatively poor when specificity was high.

1098 Ischemia-Associated Intraventricular Conduction Disturbances During Exercise Testing as a Predictor of Proximal Left Anterior Descending Coronary Artery Disease

KEVIN J. BORAN, RENE A. OLIVEROS, CHARLES A. BOUCHER, CHARLES H. BECKMANN, and JOHN F. SEAWORTH

To determine the incidence and significance of transient intraventricular conduction abnormalities occurring in association with myocardial ischemia during exercise testing, the recordings of 2,200 consecutive exercise tests were reviewed. Ten patients (0.45%) were identified as having both ischemia and intraventricular conduction abnormalities that developed transiently during the test. All 10 had both typical angina and electrocardiographic evidence of myocardial ischemia during exercise. Four had left anterior hemiblock, 2 had left posterior hemiblock, 2 had right bundle branch block, 1 had right bundle branch block and left axis deviation, and 1 had left anterior hemiblock progressing to complete left bundle branch block. Cardiac catheterization revealed significant obstruction of the proximal left anterior descending coronary artery in all patients. Eight patients were treated surgically and 2 medically, all with relief of symptoms. Nine patients had repeat exercise stress testing, all without angina or electrocardiographic evidence of ischemia and all without recurrence of the conduction disturbance. The development of intraventricular conduction disturbances with ischemia during exercise testing strongly suggests disease of the proximal left anterior descending coronary artery.

VALVULAR HEART DISEASE

1103 Determinants of the Incidence and Severity of Ventricular Arrhythmias in Aortic Valve Disease

KLAUS V. OLSHAUSEN, FRANZ SCHWARZ, JÖRG APFELBACH, NORBERT RÖHRIG, BURKHARDT KRÄMER, and WOLFGANG KÜBLER, *With the technical assistance of* SONJA GUND

Twenty-four hour ambulatory electrocardiographic recordings in 93 patients with aortic valve disease revealed a high prevalence of ventricular arrhythmias. Only 16% of all patients had no ventricular premature beats (VPB), whereas multiform VPB were found in 47 patients (51%). Paired VPB were found in 32 (34%) and ventricular tachycardia in 17 (18%) of the 93 patients studied. The occurrence of ventricular arrhythmias was not related

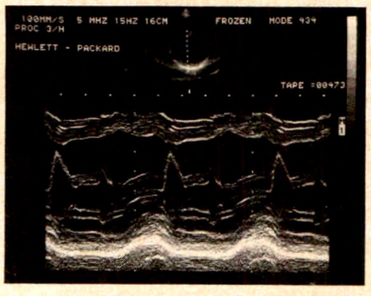
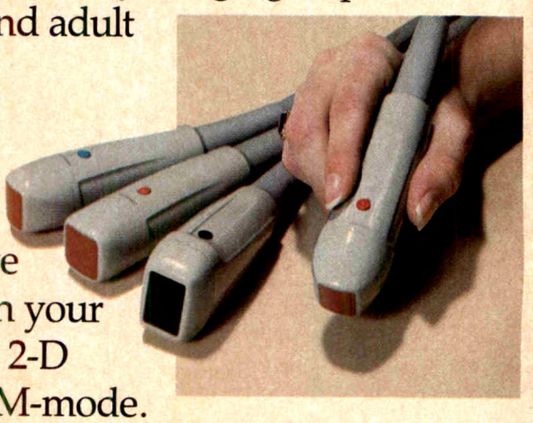
8 penetrating about any cardiac

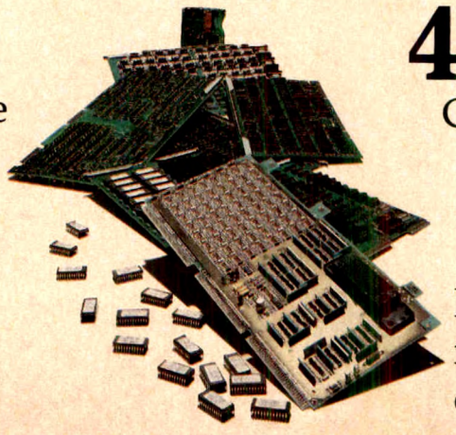
1. Does it produce high-resolution images? Hewlett-Packard's phased array Cardiac Imaging System does. Images are crisp, with well-defined boundaries, and free of artifact. Automatic focusing assures sharpness at all depths. And an extended gray scale reveals even the slightest difference in cardiac tissue.



2. What about new developments? You can upgrade the Hewlett-Packard modular system. Our latest improvement? 5MHz phased array imaging. It provides ultra-high resolution for pediatric and adult echocardiography.



3. How clinically versatile is it? Hewlett-Packard's Cardiac Imaging System can scan a wide variety of patients. Choose from five different transducers, depending on your clinical need. Display simultaneous 2-D sector and M-mode, single or dual M-mode. View the image in motion on the video screen. Tape it. Freeze it. Or generate a strip chart recording.



4. Is it reliable? Our microprocessor-based Cardiac Imaging System is highly reliable. Since the phased array system has electronic heads, there are no moving parts to break down.

questions to ask imaging system.

5. What about maintenance? The Hewlett-Packard System monitors its own performance with a series of built-in self-tests. If there's an error, it signals the operator. Problems can often be identified over the phone, minimizing downtime. Service, if needed, is both fast and economical.

6. Is it easy to use? Extremely. All controls are at your fingertips. Just set it up once, then make only fine adjustments for each patient. The system even includes a comprehensive on-line cardiac analysis package for automatic computation of cardiac parameters and generation of reports.

7. Is it mobile? The compact system can be taken where it's needed, from Echo Lab to CCU to Surgery. It's an Echo Lab on wheels.

8. Is it a solid investment? Image quality, upgradeability, versatility, reliability and Hewlett-Packard's commitment to worldwide service and support make our Cardiac Imaging System a sound investment. For more information, call your HP Sales Office and ask for the Medical Systems Department, or write to us: Hewlett-Packard, 100 Fifth Avenue, Waltham, Massachusetts 02254. Do it today. **The Ultra Sound Investment.**

Mead Johnson PHARMACEUTICAL DIVISION

to the type of valve lesion, to the transvalvular gradient in patients with aortic stenosis, or to the degree of regurgitation in patients with aortic insufficiency. The most important determinants of the incidence and severity of ventricular arrhythmias were a reduced left ventricular ejection fraction and an elevated peak systolic left ventricular wall stress. Thus, severe ventricular arrhythmias are frequently a sign of impaired left ventricular function.

1110 Left Ventricular Response to Isometric Exercise and Its Value in Predicting the Change in Ventricular Function After Mitral Valve Replacement for Mitral Regurgitation

HEIKKI V. HUIKURI, MARKKU J. IKÄHEIMO, MARKKU M. K. LINNALUOTO, and JUHA T. TAKKUNEN

Reduced left ventricular (LV) afterload and its consequent effect on the resting ejection fraction may lead to overestimation of LV function in mitral regurgitation (MR). To evaluate LV function during increased afterload of the heart, an isometric handgrip test was performed during cardiac catheterization in 15 patients with MR and 9 normal subjects. Twelve months after successful mitral valve replacement, the patients were recatheterized, and the value of preoperative stress test in predicting the change in resting ventricular function was estimated. Isometric exercise caused an increase in end-systolic wall stress, a measure of ventricular afterload, in both the MR group and the control group. The ejection fraction remained unchanged in the control group, but it decreased significantly in the MR group during exercise. A positive correlation existed between the change in ejection fraction during the preoperative stress test and the change in resting ejection fraction after mitral valve replacement. In conclusion, the isometric exercise-induced change in LV function appears to predict the influence of mitral valve replacement on LV function.

1116 Preoperative Invasive Testing in Mitral Stenosis: Indications Based on Assessment of Diagnostic Yield

MARC K. EFFRON, EDWIN L. ALDERMAN, and RICHARD L. POPP

The role of preoperative invasive testing in mitral stenosis was assessed in 82 patients undergoing cardiac catheterization for isolated mitral stenosis. The patients were diagnosed by physical examination and echocardiography, lacked clinical evidence of aortic valvular or coronary artery disease, and were considered for surgical treatment primarily to relieve dyspnea. All 38 patients in New York Heart Association functional class III and 8 of 9 patients in class IV had hemodynamic confirmation of mitral disease warranting operation. An operation was not recommended in 9 (26%) of 35 patients in class II who had normal or mildly abnormal pulmonary arterial wedge pressure. Coronary arteriography was performed in 44 patients (54%) and identified 4 patients with luminal narrowing >70%. These results suggest that preoperative invasive testing in patients with mitral stenosis is unnecessary when symptoms are moderate to severe. However, preoperative cardiac catheterization is indicated in patients with mild symptoms to prevent unnecessary or premature mitral operation.

1122 Noninvasive Diagnosis of Aortic and Mitral Valve Disease With Pulsed-Doppler Spectral Analysis

KENT L. RICHARDS, SCOTT R. CANNON, MICHAEL H. CRAWFORD, and SHERMAN G. SORENSEN

To differentiate normal from abnormal left-sided heart valves, 34 adults with 48 valve lesions proven at catheterization were examined using a 3 MHz duplex pulsed Doppler echocardiograph with 2-dimensional verification of sample volume position and on-line display of the Doppler audio spectrum. Intracardiac blood turbulence was the noninvasive indicator of disease. The specific lesion present was determined by documentation of the intracardiac location and timing of turbulence. Except for a single patient with minimal aortic regurgitation, Doppler spectral envelope areas in all normal valve sites were smaller than those measured at the same sites in the patients with aortic stenosis, aortic regurgitation, mitral stenosis, and mitral regurgitation ($p < 0.01$). High sensitivity (97%) and specificity (100%) were noted despite the presence of multiple valve lesions in 67% of the patients. The data demonstrate application of a simple, noninvasive method of acquiring and analyzing Doppler echocardiographic data which allows accurate identification or exclusion of left-sided valve disease in adults, even in the presence of multiple valve lesions.

1128 Long-Term Results of Tricuspid Valve Replacement and the Problem of Prosthetic Valve Thrombosis

CHARLES W. THORBURN, JOHN J. MORGAN, MARK X. SHANAHAN, and VICTOR P. CHANG

Seventy-one patients had tricuspid valve replacement with Starr-Edwards, Björk-Shiley, Lillehei-Kaster, or porcine xenografts over a 14-year period. Prosthetic valve thrombosis occurred in 9 patients and was significantly more common with the tilting disc valves (20%) than with the Starr-Edwards valve (4%) ($p < 0.05$). Symptoms of thrombosis were often insidious, and presentation was therefore delayed. Streptokinase therapy relieved the obstruction in 1 of 2 patients.

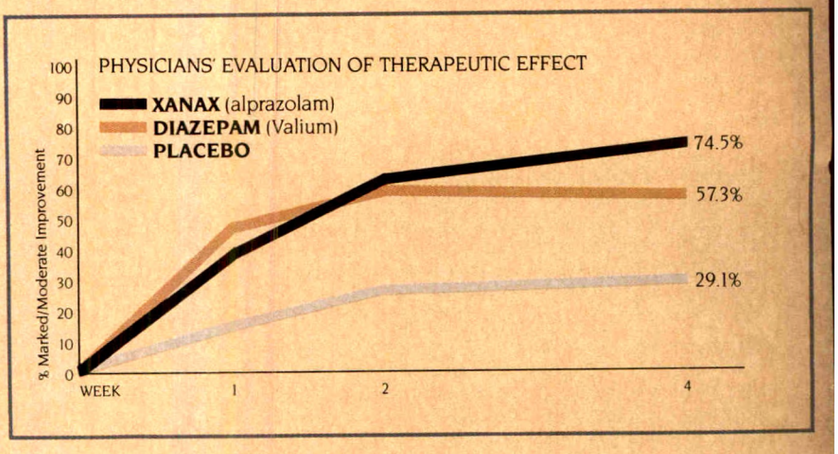
FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient,* placebo-controlled, multicenter study.*

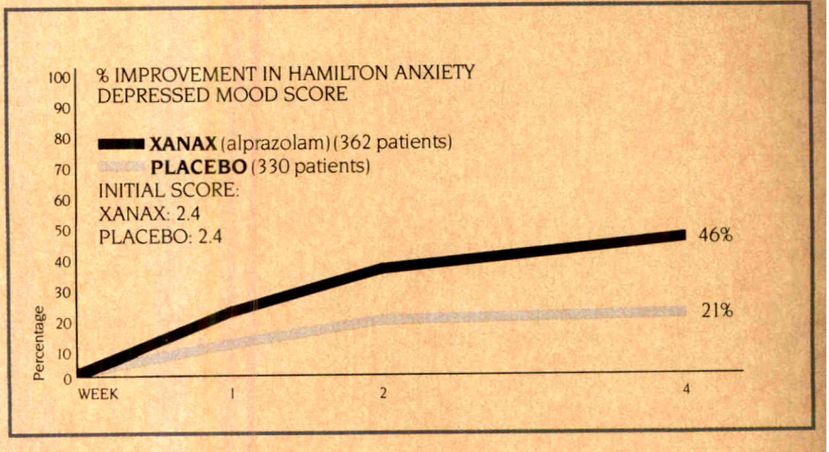


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

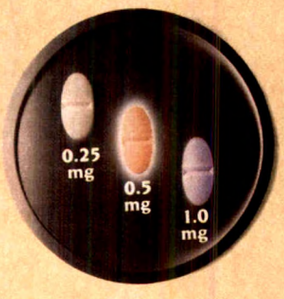
EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE: XANAX 0.25–0.5 mg T.I.D.



The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

Xanax® 0.5 mg Tablets

alprazolam Ⓒ

XANAX® Tablets ℞
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about: (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION. BS-1

*Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. J Clin Psychiatry 42 (9):347-351, 1981.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:
Bruce M. Rothschild, MD
Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 $39.50
430 pp., illus., November 1982,

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Table of contents

Section 1 - Investigative Techniques, Chapter 1 - The Rheumatologic History and Physical Examination, Chapter 2 - Arthrocentesis and Joint Fluid Evaluation, Chapter 3 - Laboratory Studies, Chapter 4 - Radiology of Joint Disease, **Section 2 - Patterns of Disease,** Chapter 5 - Infectious Agent Arthritis, Chapter 6 - Arthritis of Mechanical Derivation, Chapter 7 - Crystalline Arthritis, Chapter 8 - Rheumatoid Arthritis, Chapter 9 - Juvenile Rheumatoid Arthritis, Chapter 10 - Ankylosing Spondylitis, Chapter 11 - Reiter's Syndrome and Psoriatic Arthritis, Chapter 12 - Arthritis Associated with Gastrointestinal Disease, Chapter 13 - Endocrine, Metabolic, and Deposition Disease, Chapter 14 - Arthritis Associated with Hematologic Disease, Chapter 15 - Miscellaneous Causes of Arthritis, Chapter 16 - Nonarticular Rheumatism, Chapter 17 - Systemic Lupus Erythematosus, Polymyositis, and Sjogren's Syndrome, Chapter 18 - Scleroderma, Chapter 19 - Vasculitis/Vasculopathy, **Section 3 - Management,** Chapter 20 - Approach to Diagnosis, Chapter 21 - Compliance and Quackery, Chapter 22 - Salicylate Pharmacodynamics, Chapter 23 - Medication Therapy, Chapter 24 - Rehabilitation Therapy, Chapter 25 - Surgical Intervention

CONGENITAL HEART DISEASE

1133 Symptomatic Sick Sinus Syndrome in Children and Adolescents as the Only Manifestation of Cardiac Abnormality or Associated With Unoperated Congenital Heart Disease

STANLEY D. BEDER, PAUL C. GILLETTE, ARTHUR GARSON, Jr., CO-BURN J. PORTER, and DAN G. McNAMARA

Sick sinus syndrome occurs infrequently in children who have not undergone cardiac surgery. The symptoms, electrocardiograms, and electrophysiologic data in 11 patients aged 2 to 17 years who had nonsurgical sick sinus syndrome were reviewed. Syncope and sinus bradycardia were common presentations. Sinus nodal recovery times and atrial and atrioventricular nodal refractory periods were measured. Abnormalities of atrial and atrioventricular nodal function were demonstrated in addition to sinoatrial nodal dysfunction. Therapeutic decisions in the management of patients with symptomatic sinus nodal dysfunction should reflect these associated electrophysiologic abnormalities when they are present.

1137 Sustained Ventricular Tachycardia After Repair of Tetralogy of Fallot: New Electrophysiologic Findings

JOHN D. KUGLER, WILLIAM W. PINSKY, JOHN P. CHEATHAM, PHILIP J. HOFSCHIRE, PAUL K. MOORING, and WILLIAM H. FLEMING

Ventricular arrhythmia originating from the outflow tract of the right ventricle is a presumed cause of late sudden death in patients after repair of tetralogy of Fallot. Exercise testing has been shown to enhance detection, and phenytoin has been shown to control ventricular arrhythmias in these patients. This study reports new findings in 3 patients who underwent electrophysiologic studies at postoperative cardiac catheterization; in each, sustained ventricular tachycardia was induced and found to originate from the inflow-septal area of the right ventricle. Using serial studies, the same sustained ventricular tachycardia was induced during therapeutic serum concentrations of phenytoin but not after propranolol. No patient had ventricular arrhythmia during a 24-hour electrocardiogram or during exercise. Although no patient had normal hemodynamic function, only 1 patient had right ventricular pressure greater than two-thirds systemic pressure. Each patient had undergone initial intracardiac repair at a relatively late age (3, 9, and 9 years).

1144 Right Ventricular Function in Adults With Pulmonary Hypertension With and Without Atrial Septal Defect

MARVIN A. KONSTAM, JOHN IDOINE, JOSHUA WYNNE, WILLIAM GROSSMAN, LAWRENCE COHN, J. ROBERT BECK, JOSEPH KOZLOWSKI, and B. LEONARD HOLMAN

This study examined right ventricular (RV) function in 22 patients with pulmonary hypertension, and assessed the influence of a left-to-right shunt on systolic performance. In patients with pulmonary hypertension without volume overload (group I), RV ejection fractions, measured by radionuclide ventriculography (mean 0.35 $\pm$ 0.11) were significantly lower than in normal control subjects. In 8 patients (group II) with RV systolic pressures similar to those in group I, but with atrial-level left-to-right shunts, RV ejection fractions were normal and significantly higher than in group I. RV end-diastolic volumes were significantly greater in group II than in group I. RV ejection fractions decreased significantly in 5 patients after isolated atrial septal defect repair. The findings indicate that in patients with RV volume overload due to atrial septal defect, systolic function, measured by ejection fraction, remains normal despite pulmonary hypertension, and decreases after surgical reduction in preload.

1149 The Univentricular Heart: Combined 2-Dimensional-Pulsed Doppler (Duplex) Echocardiographic Evaluation

GEORGE S. BISSET, III and STEPHEN S. HIRSCHFELD

The combination of 2-dimensional echocardiography and pulsed Doppler echocardiography (2D/PD) has provided an extremely useful noninvasive tool in pediatric cardiology. Fourteen children with univentricular hearts were evaluated with this technique in an attempt to delineate specific morphologic and functional characteristics. Ventricular and atrial morphology, atrioventricular valve connections, and great vessel positions were accurately identified. Information concerning aortic and pulmonary flow patterns, atrioventricular valve competence, and shunt patterns could also be obtained. In several of the patients, 2D-PD evaluation provided more anatomic and functional information than angiography. It is concluded that the use of 2-dimensional echocardiography coupled with a range-gated Doppler system will improve recognition of patients with univentricular hearts and permit thorough evaluation of specific anatomic details.

CONTENTS

1155 Prognostic Value of Left Ventricular Size Measured by Echocardiography in Infants With Total Anomalous Pulmonary Venous Drainage

CARLOS OLIVEIRA LIMA, LILLIAM M. VALDES-CRUZ, HUGH D. ALLEN, SUZANA HOROWITZ, DAVID J. SAHN, STANLEY J. GOLDBERG, JESUS VARGAS BARRON, and EHUD GRENADIER

Left ventricular (LV) size may be a determinant of survival in infants with total anomalous pulmonary venous drainage (TAPVD). Right (RV) and LV size were measured by M-mode and 2-dimensional (2-D) echocardiography in 13 patients aged 1 day to 4 months who underwent surgery before age 4 months because of severe cyanosis or cardiac failure. Seven patients had venous drainage to a vertical vein; 4 had drainage to the right atrium and 2 had drainage to the inferior vena cava. Patients were divided into 2 groups: survivors (Group A, n = 8) and nonsurvivors (Group B, n = 5). Death was not statistically related to pulmonary artery pressure, pulmonary venous obstruction, age, or weight at time of surgery. RV and LV sizes at end-diastole measured from M-mode traces and 2-D echocardiographic 4-chamber views were compared with those from 15 weight-matched control infants. On M-mode and 2-D echocardiography, nonsurvivors had significantly larger RV and smaller LV dimensions than either controls or surviving TAPVD patients. The ratio of RV/LV size on M-mode and 2-D echocardiography was also different in the 3 infant groups ($p < 0.001$). RV/LV size separated nonsurvivors from survivors and controls. Postmortem examinations available in 4 of the 5 nonsurvivors demonstrated that the ratio of RV/LV size in the specimens closely agreed with the 2-D echocardiographic ratios. Our study agrees with the impression of other investigators that LV size may be a determinant of survival after repair of TAPVD.

CARDIOMYOPATHY

1160 Hypertrophic Obstructive Cardiomyopathy: Ten-to-21 Year Follow-Up After Partial Septal Myectomy

MARGARET M. BEAHRS, ABDUL J. TAJIK, JAMES B. SEAWARD, EMILIO R. GIULIANI, and DWIGHT C. McGOON

This study reviews the outcome in 36 consecutive patients who survived partial septal myectomy for hypertropic obstructive cardiomyopathy (operated on between 1960 and 1972). All patients were followed up until death or until June 1981 (mean follow-up 13.4 years). Of the 26 survivors, 17 had been more than mildly symptomatic preoperatively, but only 1 remained so postoperatively. The operation was effective in relieving the obstruction (average peak systolic gradient reduced from 79 to 8 mm Hg [$p < 0.001$]), and mitral regurgitation was relieved. No surviving patient's symptoms worsened, but 10 patients died late (4 suddenly, 5 from congestive heart failure, and 1 from a neoplasm). The 10-year survival rate was 77%. These results suggest a favorable effect of operation and support continued surgical intervention for appropriate patients.

1167 Clinical and Morphologic Cardiac Findings After Anthracycline Chemotherapy. Analysis of 64 Patients Studied at Necropsy

JEFFREY M. ISNER, VICTOR J. FERRANS, STEVEN R. COHEN, BRUCE G. WITKIND, RENU VIRMANI, JOHN S. GOTTDIENER, J. ROBERT BECK, and WILLIAM C. ROBERTS

The relation between clinical evidence of and histologic signs of anthracycline cardiotoxicity was evaluated by reviewing the clinical and morphologic findings in 64 patients studied at necropsy, all of whom had received Adriamycin or Daunomycin chemotherapy during life. In 7 (35%) of 20 patients with documented clinical toxicity consisting of impaired left ventricular systolic performance, histologic signs of cardiotoxicity were absent. Of 44 patients without clinical signs of toxicity, morphologic signs of cardiotoxicity were present in 23 (52%), mild in most patients but extensive in 4. The results of this study raise serious questions regarding the reliability of endomyocardial biopsy to monitor cardiotoxicity in patients undergoing anthracycline chemotherapy.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

1175 Mexiletine for Control of Drug-Resistant Ventricular Tachycardia. Clinical and Electrophysiologic Results in 44 Patients

LAWRENCE E. WASPE, HARVEY L. WAXMAN, ALFRED E. BUXTON, and MARK E. JOSEPHSON

This study evaluated the antiarrhythmic efficacy of mexiletine in 44 patients with recurrent drug-resistant ventricular tachyarrhythmias. Electrophysiologic testing on mexiletine alone or in combination with conventional drugs was performed in 33 patients, all of whom had inducible ventricular tachycardia (VT) during control studies. VT remained inducible with methods similar to control inductions in 25 of these patients. Only 8 patients (24%) had no inducible ventricular tachyarrhythmia on mexiletine (3) or mexiletine combined with another drug (5). Mexiletine alone or in combination with another agent suppressed VT recurrences in 5 of 11 additional pa-

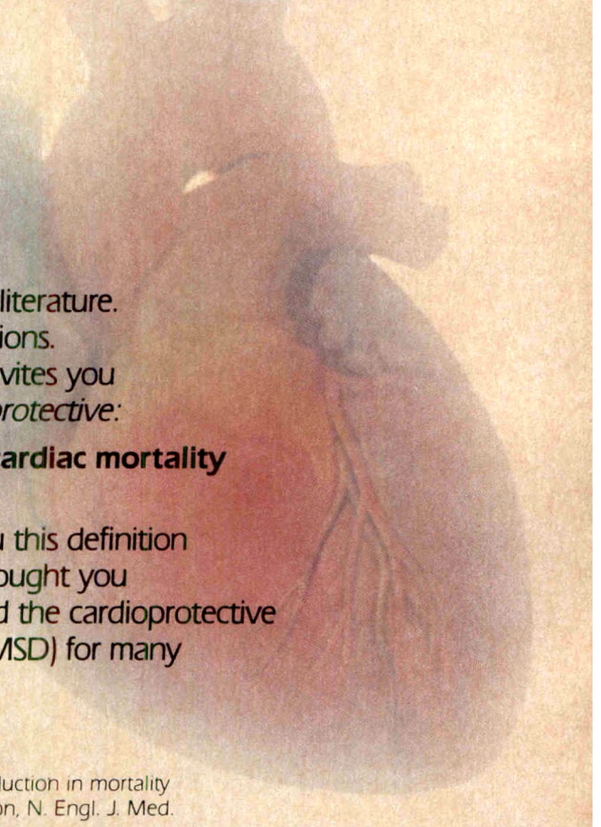
for many post-MI patients...

Cardio-protective.



Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure.

Exacerbation of Ischemic Heart Disease following Abrup Withdrawal—Hypersensitivity to catecholamines has bee observed in patients withdrawn from beta-blocker therap exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administere timolol maleate, particularly in patients with ischemic hea

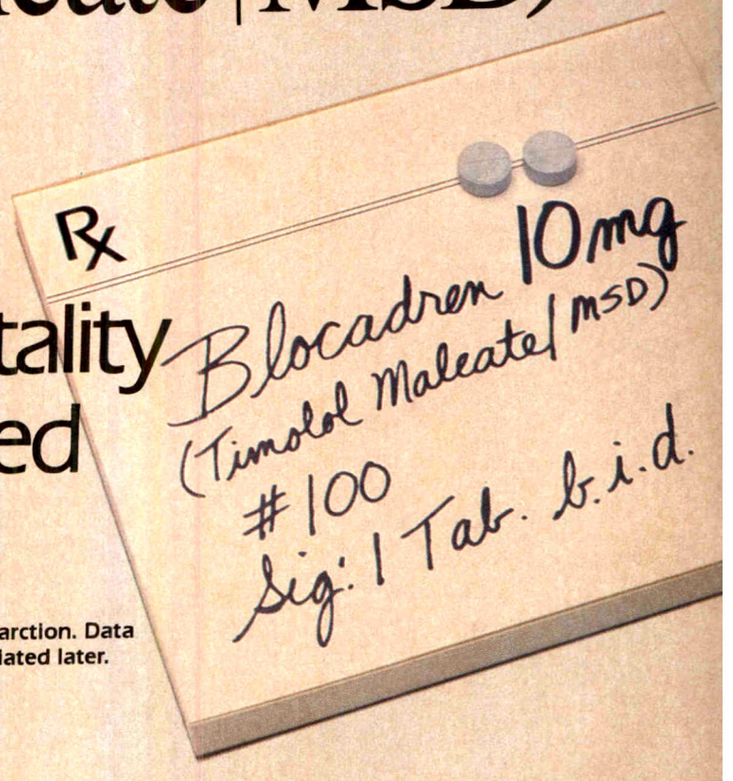
Blocadren®
Timolol Maleate (MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients



Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.

disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD

For a Brief Summary of Prescribing Information, please see next page of this advertisement.

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: Impaired Hepatic or Renal Function: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1
AV Block 2nd or 3rd degree	<1	<1	<1	<1
Sinoatrial Block	<1	<1	<1	<1
Cold Hands and Feet	8	<1	<1	0
Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.

‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

tients who did not undergo programmed stimulation. These 5 patients and the 8 patients with no inducible arrhythmia were discharged on mexiletine alone (5) or in combination with other drugs (8), and remained free of arrhythmia recurrences for a mean of 7.7 months. Adverse effects occurred in 61% of patients, and caused discontinuation of the drug in 6 patients (14%). Therefore, mexiletine alone had limited antiarrhythmic efficacy, but when combined with conventional drugs, was of some utility in 13 of 44 patients (30%). Adverse effects were frequent, and constituted a further limitation to the usefulness of mexiletine.

1182 Possible Contribution of Encainide Metabolites to the Long-Term Antiarrhythmic Efficacy of Encainide

ROGER A. WINKLE, FLORA PETERS, ROBERT E. KATES, and DONALD C. HARRISON

Twelve patients with frequent premature ventricular contractions underwent 1 year of therapy with encainide. Average suppression of premature ventricular contractions ranged from 97 to 99%. The plasma concentration of encainide metabolites exceeded that of encainide by several-fold during chronic dosing. When encainide was withdrawn at 6 and 12 months, arrhythmias did not return in many patients until well after encainide levels were undetectable. At the time of arrhythmia return considerable levels of encainide metabolites were still present in the plasma, raising the possibility that these metabolites were contributing to the drug's antiarrhythmic effect.

1189 Beat-to-Beat Left Ventricular Performance in Atrial Fibrillation: Radionuclide Assessment With the Computerized Nuclear Probe

JAMES SCHNEIDER, HARVEY J. BERGER, MILTON J. SANDS, ANTHONY B. LACHMAN, and BARRY L. ZARET

Left ventricular (LV) ejection fraction and relative LV volumes were evaluated on a beat-to-beat basis with the computerized nuclear probe, an instrument with sufficiently high sensitivity to allow continuous evaluation of the radionuclide time-activity curve. Consecutive beats were analyzed in each of 18 patients. The mean LV ejection fraction was 17 to 51%. There was substantial beat-to-beat variation in cycle length and LV ejection fraction in all patients, including those with marked LV dysfunction. There was an excellent correlation between mean ejection fraction derived from the nuclear probe and gated ejection fraction obtained by gamma camera imaging ($r = 0.91$). Based on beat-to-beat analysis, LV function was dependent on relative end-diastolic volume and multiple preceding cycle lengths, but not preceding end-systolic volumes. This study demonstrates that a single value for LV ejection fraction does not adequately characterize LV function in atrial fibrillation.

1196 Comparative Effects of Beta-Adrenergic Blocking Drugs on Experimental Ventricular Fibrillation Threshold

JEFFREY L. ANDERSON, HUGO E. RODIER, and LARRY S. GREEN

Clinical studies have suggested that certain beta-blocking agents may reduce sudden death in postinfarction patients, but the mechanism is unknown. In this study, canine ventricular fibrillation thresholds were measured before and after intravenous administration of various doses of representative beta-blocking drugs or saline solution. Thresholds were also determined 3 minutes after ligation of the mid-anterior descending coronary artery. Significant increases in ventricular fibrillation thresholds occurred, both with and without ischemia, with each beta-blocker tested, averaging up to 6-fold. However, the minimal effective doses at which maximum effects occurred varied widely, in the following order: timolol >pindolol >propranolol ≥metoprolol >labetolol. Beta-blocking potencies thus were better predictors of relative antifibrillatory potencies than were individual accessory drug properties. Interruption of cardiac sympathetic stimulation was shown to account for part of the antifibrillatory effect. Elevation in ventricular fibrillation threshold may be an important mechanism by which beta-blockers reduced cardiac mortality in ischemic heart disease.

1203 Effects of Exercise and Isoproterenol During Atrial Fibrillation in Patients With Wolff-Parkinson-White Syndrome

LAWRENCE D. GERMAN, JOHN J. GALLAGHER, ARCHER BROUGHTON, TOM GUARNIERI, and JOEY L. TRANTHAM

Exercise and isoproterenol infusion were studied during atrial fibrillation in 17 patients with Wolff-Parkinson-White syndrome to assess their effects on conduction over the accessory atrioventricular connection. Exercise favored conduction over the atrioventricular node and resulted in a lesser degree of preexcitation. Isoproterenol allowed rapid ventricular responses to be achieved in some patients not previously demonstrating rapid conduction over the accessory pathway. This study demonstrates the usefulness of isoproterenol infusion in patients with Wolff-Parkinson-White syndrome for assessing the risk of developing rapid ventricular rates during atrial fibrillation.

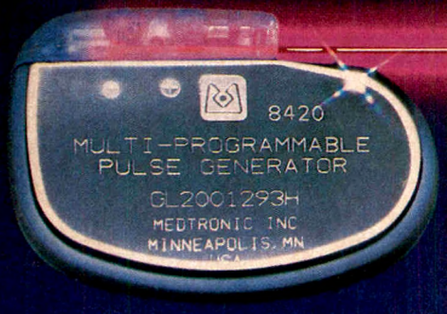
S P E C T R

THE WORLD'S MOST PRESCRIBED PACEMAKER

THRESHOLD MARGIN TEST.

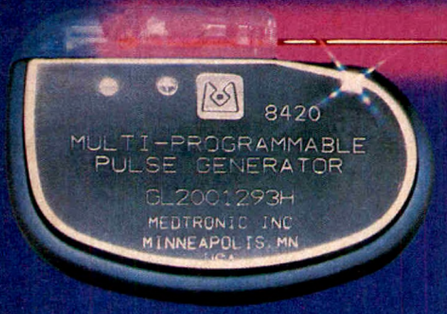
Insure adequate threshold safety margins—even over the telephon



A 66 year old female patient on vacation calls your office long distance for a routine pacer check. Are the pacing pulses sufficient to stimulate her heart? Here's how the unique Spectrax SXT™ **threshold margin test** helps you. Your patient simply positions the magnet she carries over her pacemaker and the Spectrax SXT automatically performs the test. Energy in the 3rd of 3 pulses emitted at 100 **ppm** is reduced 25% with no loss of capture, indicating an adequate safety margin. Long distance diagnosis is complete and your patient enjoys peace of mind.

AUTOMATIC THRESHOLD MEASUREMENT.

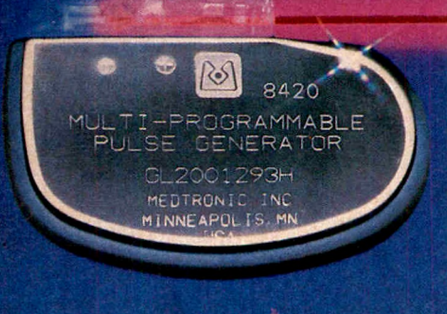
Determine pacing energy levels—fast.



You suspect loss of capture in a 62 year old male referral patient. What energy levels are needed for effective pacing stimulation of his heart? The exclusive **threshold measurement** built into his Spectrax SXT™ pacemaker gives you the answers fast. With the advanced Medtronic® CENSYS™ programmer, **automatic threshold measurement** is a simple pushbutton procedure. Reducing pulse width to the point of capture/loss tells you within 0.1 **ms** your patient's threshold. Restore original pulse width with no reprogramming needed and adjust to guarantee capture. Simple, convenient and electronically precise. That's Spectrax SXT's **automatic threshold measurement** feature.

PULSE GENERATOR BATTERY DEPLETION WARNING.

(EOL). 3 distinct warnings signal elective replacement.



Your 70 year old female patient has rushed to your office in alarm. During her routine pulse self-check test, she determined that her pacemaker had dropped 10% in rate. The implanted unit is a Spectrax SXT though, and you are able to reassure her. This rate change is simply a safeguard warning signalling elective replacement. Pulse width on the Spectrax SXT automatically increases to compensate for the gradual decline in battery voltage. She is in no danger of pacemaker battery failure or loss of capture. This fact is easily and visibly confirmed with Spectrax SXT's noteworthy telemetry which prints out battery status on command. In this case the print out has changed from **"Battery OK"** to **Elec. Replace Time!** Seeing is believing. You and your patient have several months in which to make her surgery decision. You can confidently relieve her anxiety.

Medtronic

Medtronic Implantable Pulse Generators and Leads

Intended Uses

Ventricular pacing using an implantable ventricular pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems. Cardiac pacing using an implantable A-V sequential pulse generator is for long-term therapeutic control of heart rate in patients where restoration of A-V synchrony is indicated to improve cardiac output or to protect against arrhythmias related to sequence of cardiac impulse propagation.

Contraindications

There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings

Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. See the specific precautions and warnings in the technical manuals included with the pulse generator.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

MISCELLANEOUS TOPICS

1207 Prevalence and Correlates of Posterior Extra Echocardiographic Spaces in a Free-Living Population Based Sample: The Framingham Study

DANIEL D. SAVAGE, ROBERT J. GARRISON, FREDERICK BRAND, SANDRA J. ANDERSON, WILLIAM P. CASTELLI, WILLIAM B. KANNEL, and MANNING FEINLEIB

To obtain epidemiologic information on extra echocardiographic spaces immediately posterior to the left ventricular free wall, 2,028 subjects in the original Framingham cohort study (mean age 70 ± 7 years) and 3,624 of the offspring of the cohort (and their spouses) (mean age 44 ± 10) with adequate echocardiograms were evaluated. Extra echocardiographic spaces were detected in 370 (6.5%) of the 5,652 subjects. The prevalence ranged from <1% in subjects in the 20- to 30-year age decade to >15% for those in their 80s. Extra echocardiographic spaces tended to be more common in subjects who were older, female, obese, and more hypertensive, and those who had higher blood sugar and higher low density lipoprotein cholesterol levels (measured 8 years earlier). Extra echocardiographic spaces were significantly and independently associated with age and obesity in multivariate analysis. The possibility that such extra echocardiographic spaces may often represent subepicardial fat rather than pericardial fluid deserves further study.

1213 Effect of Verapamil on Left Ventricular Function: A Randomized, Placebo-Controlled Study

RONALD E. VLIETSTRA, MARIA A. C. FARIAS, ROBERT L. FRYE, HUGH C. SMITH, and ERIK L. RITMAN

The effects of verapamil on left ventricular function were tested in 25 patients with suspected coronary artery disease. A double-blind, randomized, placebo-controlled study design was used. Verapamil (0.2 mg/kg over 10 minutes) significantly lowered mean arterial pressure while increasing the cardiac index. No statistically significant effect was seen on heart rate, left ventricular end-diastolic pressure or end-systolic volume index, ejection fraction, peak rates of systolic wall thickening or diastolic wall thinning, or percentage of hemiaxial shortening. However, there was a small increase in the left ventricular end-diastolic volume index. The study demonstrates that verapamil acutely reduces systemic vascular resistance, increases left ventricular end-diastolic volume index (consistent with a negative inotropic effect), and does not appear to improve regional wall dynamics in portions of the left ventricular wall considered hypokinetic because of myocardial ischemia.

1218 Hemodynamic and Electrocardiographic Effects in Man of a New Nonionic Contrast Agent (Iohexol): Advantages Over Standard Ionic Agents

G. B. JOHN MANCINI, J. NEUKAM BLOOMQUIST, VALMIK BHARGAVA, JOSEPH B. STEIN, WILBUR LEW, ROBERT A. SLUTSKY, RALPH SHABETAI, and CHARLES B. HIGGINS

Iohexol is a new, nonionic contrast material that has been shown in animal studies to hold great promise as an agent for coronary arteriography and ventriculography with fewer adverse effects than standard ionic media. It has not yet been systematically studied in man. Fifty patients referred for elective cardiac catheterization were randomized to receive either iohexol or meglumine sodium diatrizoate (Renografin®-76). Hemodynamic and electrocardiographic measurements were made after left ventriculography and both left and right coronary arteriography. Iohexol produced fewer deleterious hemodynamic and electrocardiographic changes. This favorable preliminary experience in man has potential clinical importance because of the large number of patients undergoing angiographic procedures.

1223 Increased Left Ventricular Function as an Adaptive Response in Vibration Disease

TSUNETAKA MATOBA, MORIO ITAYA, KOJI TOYOMASU, TAKEYOSHI TSUIKI, HIRONORI TOSHIMA, and HIROSHI KUWAHARA

Left ventricular function was studied in 35 patients with vibration disease and 35 age-matched healthy subjects. The average age was 49 years. The left ventricular ejection fraction (EF) in vibration disease by the method of echocardiography was 89 ± 4%, which is significantly higher than in the control subjects ($p < 0.01$). EF tended to increase with the increases in the level of autonomic nerve activity. The stroke volume index in patients with vibration disease was also significantly larger than in the controls ($p < 0.001$). Electrocardiographically, the ratio of T waves to R waves in precordial leads was larger than in the controls. Resting heart rate in the vibration disease was significantly lower than in the controls ($p < 0.001$). These findings suggest that the cardiovascular system in vibration disease due to vibration, noise, and cold provides an adaptive response to the stressors.

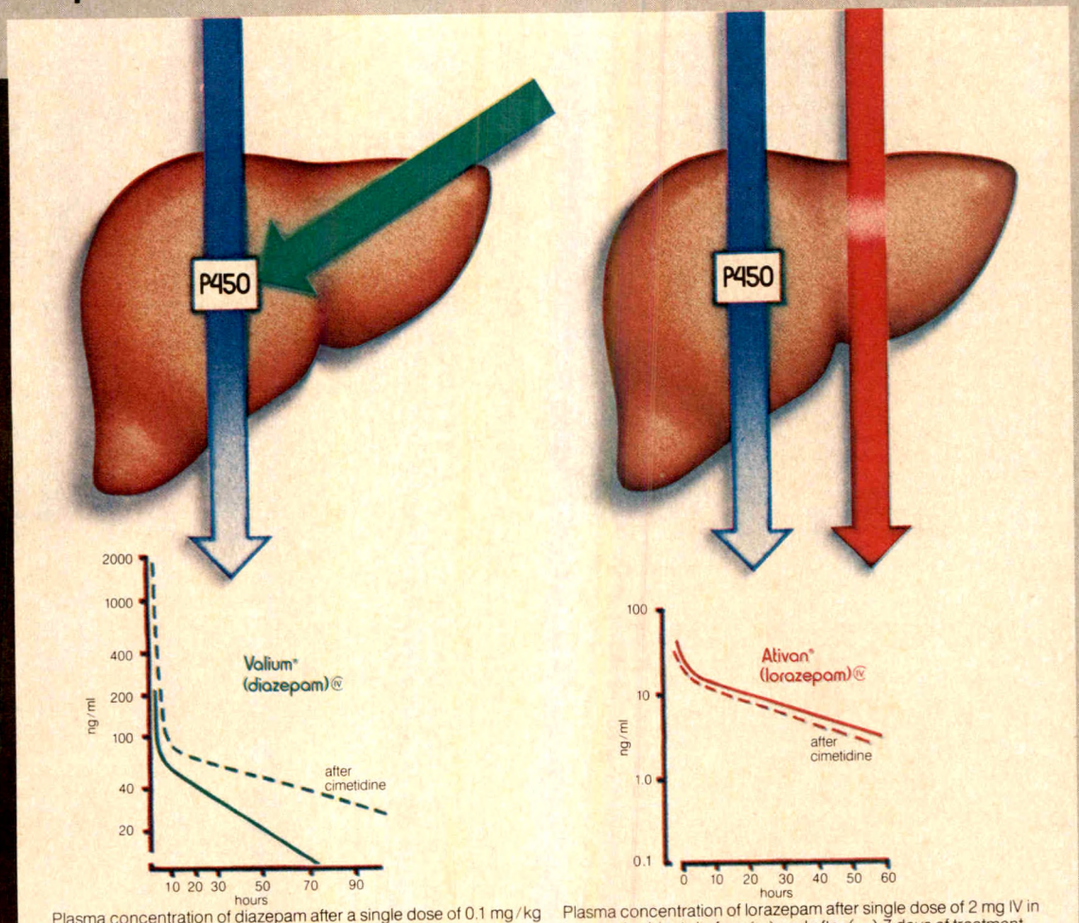
Ativan®: Agent of Change
(lorazepam)



Plasma concentration of diazepam after a single dose of 0.1 mg/kg IV to a single subject administered before (—) and after (---) pretreatment with cimetidine—5 X 200 mg orally q6h. (Adapted from Klotz U, Reimann I: N Engl J Med *302*:1012-1014, 1980.)

Plasma concentration of lorazepam after single dose of 2 mg IV in 8 normal subjects before (—) and after (---) 7 days of treatment with cimetidine, 300 mg orally qid. (Adapted from Patwardhan RV, Yarborough GW, Desmond PV, et al: Gastroenterology *79*:912-916, 1980.)

because it doesn't utilize the P450 system

All drugs inactivated by oxidative metabolism, including cimetidine and most benzodiazepines, utilize the cytochrome P450 oxidase enzyme system and, therefore, compete for it when given concomitantly. Patients on cimetidine, for example, are apt to experience excessive drowsiness when taking a benzodiazepine dependent on this system—because benzodiazepine clearance is delayed and plasma levels increase.

Ativan® (lorazepam) is inactivated by simple, one-step glucuronidation and is not subject to N-dealkylation or hydroxylation by the P450 system—unlike diazepam, chlordiazepoxide, clorazepate and prazepam, all CIV.

And, since Ativan does not compete for the P450 system, its elimination is not appreciably affected by concomitant use of cimetidine... one more reason why Ativan is becoming the anxiolytic of choice for an increasing number of physicians.

Ativan®
for (lorazepam)℞ IV
Anxiety

The appearance of these tablets is a trademark of Wyeth Laboratories.

NEW TABLET DESIGN 0.5 mg and 1 mg

(2 mg tablet retains original oval shape at present)

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

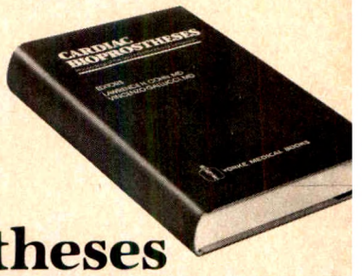
Ativan® (lorazepam) for Anxiety

DOSAGE: Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.

HOW SUPPLIED: 0.5, 1.0 and 2.0mg tablets.

Wyeth Laboratories

The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposiu Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposiu on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* in formation on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and wh is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professiona library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982.*

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surger Departments of Cardiovascular Surgery and Cardiology, Univer sity of Padova Medical School, Padova, Italy.

The ECG cartridge with 50 lives.

DEL MAR AVIONICS

onventional 24-hour Holter reel tapes ave less than 9 lives. And cassettes are commended only for single use.

But our advanced design, four-hannel cartridge, when used with the eries 449 Electrocardiocorder® ystems, may be erased and re-used for to 50 ambulatory recordings.

The reasons?

The cartridge has been specifically esigned with extended tape life in mind. ombining the convenience of a cassette ith the accuracy of a reel-to-reel design, ie cartridge tape can be manipulated today's high scanning speeds with exact recision. Moreover, precise data man-gement can be attained without tape retching or twisting, increasing tape life at least ten-fold.

Precise time coding, using a proprietary digital encoding process, ensures timing accuracy to within one second throughout the entire 24-hour recording. And the magnetic characteristics of the tape itself are matched exactly to the dynamic range of our analyzers. Total system compatibility gives you optimal fidelity.

And if that's not enough, one of the cartridge channels can be used to record ambulatory blood pressure, further extending your diagnostic capability.

For more details on the four-channel cartridge that gives you added life, superior fidelity and BP capability, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, California 92714, Telephone (714) 549-1500, or call toll free at (800) 854-0481, (in California 800/432-8446), Telex: 68-5621.

CORONARY HEART DISEASE

Late Prognostic Value of Scintigraphic Parameters Of Acute Myocardial Infarction Size in Complicated Myocardial Infarction Without Heart Failure

ELIAS H. BOTVINICK, MD, JUAN F. PEREZ-GONZALEZ, MD, PhD, RICHARD DUNN, MD, THOMAS PORTS, MD, KANU CHATTERJEE, MD, and WILLIAM PARMLEY, MD

Perfusion scintigraphy with thallium-201, infarct scintigraphy with technetium-99m pyrophosphate (TcPYP), and equilibrium blood pool scintigraphy were performed during the initial hospitalization for acute myocardial infarction (MI) in 25 patients without evidence of heart failure who presented with advanced electrocardiographic rhythm and conduction disturbances requiring treatment. Scintigraphic findings during short-term hospitalization were related to the late clinical follow-up performed an average of 14 months later, where patients were grouped as asymptomatic, 8 patients; symptomatic, 9 patients; and deceased, 8 patients. Quantitation of perfusion abnormalities, TcPYP image abnormalities, and left ventricular ejection fraction (EF) revealed that the deceased group had significantly larger TcPYP abnormalities (36 ± 20 cm^2), absolute perfusion abnormalities (32 ± 16 cm^2), and perfusion abnormalities expressed as a percentage of the projected left ventricular area (42 ± 8%) than the asymptomatic group (13 ± 8 cm^2, 14 ± 6 cm^2, and 20 ± 9%; $p < 0.05$, $p > 0.05$, and $p < 0.01$, respectively). The percent perfusion abnormality was significantly larger in the deceased group (42 ± 8%, $p < 0.01$) than in either the symptomatic group (35 ± 13%, $p < 0.01$) or the asymptomatic group (20 ± 9%), and this parameter in the symptomatic group also differed from that in the asymptomatic group ($p < 0.01$).

The study indicates that patients with rhythm and conduction disturbances and without congestive heart failure during acute MI may follow an uncomplicated or a complicated late clinical course. Early scintigraphic measurements of MI and perfusion correlate well with this outcome; however, EF could not differentiate among prognostic subgroups.

Death during an acute myocardial infarct (MI) and prognosis after the event have been related to MI size.[1–3] Several noninvasive clinical and laboratory parameters, including precordial S-T segment mapping[4,5] and enzymatic measurements,[6,7] have met limited success as measures of acute MI size.[5,8] Scintigraphic parameters of acute MI size have been related to the location and extent of necrosis in both animals and man.[9,10] Recently, acute MI size, as assessed by technetium-99m pyrophosphate (TcPYP) scintigraphy,[11,12] perfusion scintigraphy,[13,14] and indirect scintigraphic parameters of left ventricular function, particularly ejection fraction [EF],[15] have been associated with both early and late prognosis after acute MI.

From the Department of Medicine, Division of Cardiology, the Department of Radiology, Section of Nuclear Medicine, and the Cardiovascular Research Institute of the University of California at San Francisco. This study was supported in part by Grant HL 21793 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland, a grant from the Fannie Ripple Foundation, Morristown, New Jersey. Dr. Botvinick is supported in part by a Grant-in-Aid from the George D. Smith Foundation, San Francisco, California, and is a recipient of the American Heart Association Established Investigator Award. Dr. Dunn is a recipient of an Overseas Clinical Fellowship from the National Heart Foundation of Australia, Sydney, Australia. Manuscript received July 6, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

Address for reprints: Elias H. Botvinick, MD, Department of Medicine, 1186 Moffitt Hospital, University of California at San Francisco, San Francisco, California 94143.

Among clinical parameters which have been related to prognosis after acute MI, disturbances of cardiac rhythm[16–18] and conduction[19,20] appear prominent. In addition, both rhythm and conduction disturbances are known contributors to sudden death[21] and are frequently related to heart failure, where the prognostic impact is compounded.[22] However, the late prognosis of patients with rhythm and conduction disturbances but without heart failure early after MI may be difficult to predict early. The purpose of this study was to determine whether scintigraphic measurements of acute MI size, perfusion abnormalities, and left ventricular function, measured early after the event, could be related to the late prognosis in such patients.

Methods

Patient population: From a larger group of 62 consecutive patients admitted to the coronary care unit with acute MI and studied prospectively with scintigraphic techniques, 25 patients were found to have rhythm and conduction disturbances in the absence of heart failure; they form the basis of this report. Patients with acute MI were included if, in the absence of symptoms or signs of heart failure, they presented with rhythm disturbances defined as ventricular fibrillation, ventricular tachycardia, complex premature ventricular contractions of Lown classification 3 or higher,[17] atrial fibrillation or flutter requiring treatment, and/or conduction disturbances, including second- and third-degree atrioventricular block requiring a pacemaker or bifascicular bundle branch block. There were 20 men and 5 women with a mean age of 61 years (range 37 to 88). As for the group as a whole, the diagnosis of acute MI in this subgroup was based on at least 2 of the following 3 criteria: (1) a history of typical prolonged chest pain; (2) electrocardiographic (ECG) changes indicative of myocardial injury including S-T depression ≥1.0 mm, T-wave inversion persisting for ≥24 hours, a newly developed QS complex or Q waves ≥0.04 second; (3) characteristic elevation of total creatine kinase to a peak level ≥90 IU/liter or MB component ≥4% of the total creatine kinase, or both. Serum enzyme determinations were performed on admission, then every 4 hours for 24 hours, and then every 6 hours to 72 hours. Creatine kinase was measured by a fluorometric method[23] and creatine kinase-MB by an electrofluoretic method.[24] Historical and ECG evidence of previous MI was sought.

Acute MI was diagnosed as transmural with the appearance of new QS complexes or Q waves ≥0.04 second and subendocardial with T-wave inversion or S-T segment depression or both, persisting for ≥24 hours without loss of R-wave voltage or development of new Q waves. The location of acute MI was determined in all patients using standard ECG criteria[25] and chest pain was categorized by the standards of the New York Heart Association.[26]

Patients were added to the study over a 3-year period. Patients were excluded if imaging was unavailable or if they presented to the coronary care unit more than 48 hours after the event or had evidence of heart failure including symptoms of shortness of breath, paroxysmal nocturnal dyspnea, orthopnea, pulmonary rales, ventricular gallop, or radiographic pulmonary blood flow redistribution. Similarly, patients presenting with shock or other conditions which required aggressive medical or surgical therapy and prevented patient participation or which made them intolerant to the multiple imaging procedures were excluded. All studies which were not clinically indicated for patient evaluation were obtained after the administration of full verbal and written informed consent.

Scintigraphic studies: Scintigraphic studies were done as soon as possible after infarction in accordance with clinical and technical restraints. All studies were performed during the acute phase of hospitalization within 10 days of the event; 60 (86%) of 70 scintigraphic studies were performed within the first 4 days of symptom onset. The latter included 22 of 25 MI scintigrams, 20 of 22 perfusion scintigrams, and 18 of 23 blood pool scintigrams.

Owing to clinical and technical restraints, 3 of the 25 patients did not have perfusion imaging, and 2 patients did not have blood pool scintigraphy.

All scintigraphic studies were performed on a Series 120 portable (Ohio Nuclear Corporation, Solon, Ohio; now a Division of Technicare) or a Pho Gamma V stationary scintillation camera (Searle Radiographics, Des Plaines, Illinois; now a Division of Siemens). Both perfusion scintigraphy using thallium-201 and MI scintigraphy using TcPYP were performed in 30° right anterior oblique, anterior 45° left anterior oblique, 60° left anterior oblique, and left lateral projections. Perfusion scintigraphy was performed 10 minutes after the intravenous injection of 1.5 to 2 mCi of thallium-201 employing a high-sensitivity collimator. The projection of the initial perfusion scintigram was acquired to 300,000 counts with each subsequent projection obtained to isotime. Infarct scintigrams were acquired according to a similar methodology 2 to 4 hours after the intravenous administration of 15 to 20 mCi of TcPYP using a low energy all-purpose collimator. Equilibrium blood pool scintigrams were initially performed using technetium-99m albumin in a dual-gated mode to a total of 400,000 counts in 40 ms end-diastolic and end-systolic frames acquired in 30° right anterior oblique and 60° left anterior oblique projections. In the most recent 18 patients, blood pool scintigraphy was performed with in vivo labeled red cells using standard multiple-gated methodology and a 28-frame multiple-gated movie acquired to a total of 4.5 million counts in both a 30° right anterior oblique and the "best septal" left anterior oblique projection; the latter best separated the right and left ventricles. While perfusion and infarct scintigrams were analyzed from analog polaroid images, initial blood pool studies were evaluated for the ejection fraction calculated from the geometric biplane method.[27] Later studies were acquired on a PDP 1140 (Digital Equipment, Maynard, Massachusetts) computer where counts ejection fraction was calculated according to standard methodologic methods from the best septal left anterior oblique image projected on a 128 × 128 matrix on a high quality Conrac (DeAnza, Burlingame, California) display.

The largest projected abnormality on both infarct and perfusion scintigrams was planimetered by 2 observers without knowledge of the clinical course and expressed in square centimeters using the field of view to calibrate the abnormality. The 2 observers agreed within 5% in their measured evaluation in 85% of cases. In the remainder, the area of abnormality was decided by agreement between the 2 observers. Perfusion abnormalities were also expressed as a percentage of the projected left ventricular area. Figure 1 demonstrates MI and perfusion scintigrams and their quantitation in a patient with a large lateral scintigraphic MI.

Clinical course and follow-up: All 25 patients survived the initial hospitalization and were followed for an average of 14 months (standard deviation 8 months, range 2 to 34). Two patients underwent coronary artery bypass graft surgery 2 and 14 months after their acute MI and were considered to end their follow-up period at the time of surgery. Patients were followed periodically at the University of California, San Francisco Cardiac Clinic, or by means of personal discussion with their outside physician and next of kin. Deaths were noted as cardiac if so recorded by the patient's physician or if occurring suddenly in the absence of symptoms or within

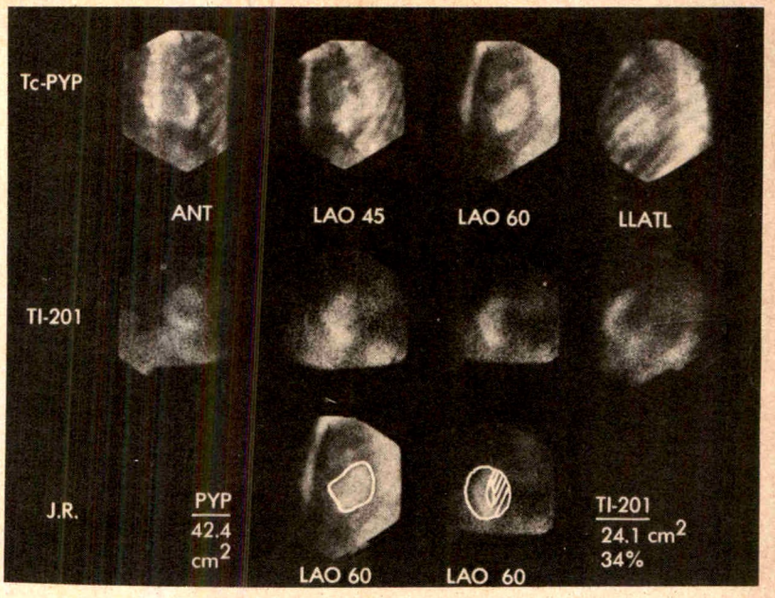

FIGURE 1. Scintigraphic sizing of acute myocardial infarction. Shown in the **upper panel** are TcPYP scintigrams and in the **center panel** thallium-201 (TI) myocardial perfusion scintigrams performed in anterior (ANT), 45° and 60° left anterior oblique (LAO), and left lateral (LLATL) projections in a patient with a large acute anterolateral myocardial infarction. In the **bottom panel,** the abnormal TcPYP area is outlined and expressed in cm^2. The perfusion image abnormality is similarly identified and expressed as an absolute abnormality and as a percentage of the projected left ventricular myocardium. J.R. = Patient 10 (see Table I).

6 hours of their appearance in the absence of another cause.

According to the long-term clinical course, determined by the follow-up protocol, patients were classified into 3 groups: (1) the asymptomatic group, composed of patients who, after hospital discharge, had no symptoms requiring treatment; (2) the symptomatic group, composed of patients who, at any time after hospital discharge, had anginal chest pain that required treatment or who had symptoms or signs of congestive heart failure as described above and which required treatment; (3) the deceased group, composed of patients who died of cardiac causes during the follow-up period. Both patients who underwent coronary artery bypass graft surgery had angina on follow-up, 1 in association with congestive heart failure.

Data analysis: To assess the prognostic value of scintigraphic indicators obtained early during initial hospitalization for acute MI, with respect to the long-term clinical course of patients after discharge, quantitative scintigraphic data from TcPYP infarct scintigrams, thallium-201 perfusion scintigrams, and blood pool scintigrams were consolidated according to the clinical group. Means and standard deviations of measurements of MI size, perfusion abnormalities, and left ventricular EF were calculated for the group of patients who died, for all patients who were alive at the time of last follow-up and who were symptomatic with angina or heart failure, and for all patients who were alive at the time of last follow-up and entirely asymptomatic. Quantitative differences in the size of scintigraphic abnormalities and ejection fractions were analyzed by means of a 1-way, nonweighted means analysis of variance. The between-groups variations were partitioned using planned or orthogonal comparisons: asymptomatic versus deceased, asymptomatic versus symptomatic, and symptomatic versus deceased. In addition, to compare all possible pairs of groups, a Student-Newman-Kuhles test was carried out. The scintigraphic indicators thus identified to be significantly different between groups were further analyzed by establishing absolute "break point" values which could be used to prospectively classify patients in those groups. For the deceased group, these break point levels were selected by determining the values of each scintigraphic indicator which yielded optimal detection of patients who died. With break point levels determined in this manner, each indicator was tested for accuracy of prediction of death or survival and development or absence of symptoms. Positive and negative predictive values were calculated as the number of patients with a given range of scintigraphic abnormality who were correctly classified divided by the total number of patients with this range of scintigraphic abnormality. Finally, the predictive accuracy of scintigraphic indicators was compared with that of clinical and historical variables.

Results

Among the 25 patients studied, 14 had an inferior MI and 11 an anterior MI. The MI was transmural in 22 and nontransmural in 3. There were 7 patients with a prior MI. The clinical findings on late follow-up in our 25 patients are detailed in Table I. On follow-up, 8 patients remained entirely asymptomatic, while 9 patients had symptoms, 2 patients had angina alone, 3 had congestive heart failure alone, and 4 had angina and congestive heart failure in the follow-up period. Among those in whom congestive failure developed, 2 patients were known to have another MI. Among those who died, 2 patients had sudden death and 4 had renewed chest pain, 1 of these with another MI and 3 with worsening heart failure. There was no significant relation between age, sex, site of MI, transmural nature of MI, the presence of prior MI, or the peak level of serum creatine kinase and the subsequent clinical findings on late follow-up. Both in our overall population of 62 patients[14] and among the 25 patients studied here, there was no relation between the size of scintigraphic abnormality and the time of imaging after the onset of symptoms.

Sixteen patients had rhythm disturbances; 5, conduction disturbances; and 4, combined rhythm and conduction abnormalities. Table II enumerates the individual rhythm and conduction abnormalities noted during the short-term hospitalization for acute MI and relates these to the late prognosis. Ventricular arrhythmias were not associated preferentially with any of the follow-up groups. However, both atrial arrhythmias and bifascicular block occurred in patients who later died or had symptoms, while heart block, requiring pacemaker insertion, appeared to be associated with a

more benign clinical course in this late follow-up study.

Patients in the deceased group had significantly larger TcPYP abnormalities (36 ± 20 cm^2), absolute perfusion abnormalities (32 ± 16 cm^2), and percent left ventricular involvement (42 ± 8%) on perfusion scintigraphy than the asymptomatic group (13 ± 8 cm^2, 14 ± 6 cm^2, and 20 ± 9%; $p < 0.05$, $p < 0.05$, and $p < 0.01$, respectively). While the absolute abnormality on TcPYP scintigraphy and perfusion scintigraphy was larger in the symptomatic group than in the asymptomatic group, it was not significantly different. In the symptomatic group only the percent left ventricular involvement on perfusion scintigraphy (35 ± 13%) was significantly larger than in the asymptomatic group (20 ± 9%, $p > 0.01$). The left ventricular EF was not significantly different between groups and could not differentiate asymptomatic survivors from symptomatic survivors or those who died. Perfusion scintigraphic abnormalities expressed as a percentage of left ven-

TABLE II Rhythm and Conduction Abnormalities: Relation Between Rhythm and Conduction Disturbances and Late Clinical Course

Late Clinical Course	Rhythm Abnormalities				Conduction Abnormalities

Asymptomatic (n = 8)	3	2	1	0	4	0
Symptomatic (n = 9)	1	2	2	3 (1)	0	2
Died (n = 8)	2	0	2	5 (2)	1	2
Total (n = 25)	6	4	5	8 (3)	5	4

Parentheses indicate patients with both atrial and ventricular arrhythmias.
AF = atrial fibrillation; AFL = atrial flutter; PVC = premature ventricular contraction; VF = ventricular fibrillation; VT = ventricular tachycardia.

tricular involvement were significantly larger both in the deceased group (42 ± 8%, p <0.01) and the symptomatic group (35 ± 13%, p <0.01) than in the asymptomatic group (20 ± 9%). Enzyme levels failed to differentiate the groups. These findings are summarized in Figure 2.

Breakpoint values of 20 cm^2 for the absolute perfusion abnormality and 33% for the perfusion abnormality expressed as a percentage of left ventricular involvement succeeded in identifying 7 of 8 asymptomatic survivors who had absolute perfusion abnormalities <20 cm^2 or 33%. These values also succeeded in identifying 5 of 8 symptomatic survivors and 5 of 6 patients among those who died who had absolute perfusion abnormalities >20 cm^2 or which projected as >33% of the left ventricular area. Similarly, a breakpoint value of 25 cm^2 for the absolute size of the TcPYP infarct abnormality identified all 8 asymptomatic survivors, each of whom had scintigraphic infarct size <25 cm^2, and also identified 5 of 9 symptomatic survivors and 6 of 8 patients who died with scintigraphic infarct size >25 cm^2.

Discussion

Acute MI size has been shown to be related to the clinical outcome after the event.[2] A reliable noninvasive method for estimating acute MI size can have significant prognostic impact in patients. Initial studies would indicate that scintigraphic variables offer a relatively convenient, noninvasive marker for myocardial infarction size[9,10,28,29] and are shown in this study to allow identification of important clinical subgroups.

Advanced arrhythmias and conduction abnormalities occur frequently after MI and often appear to be related to severe abnormalities of ventricular function and a generally reduced prognosis.[19,22] The current investigation employed scintigraphic studies to separate, for the first time, poor and good prognosis subgroups from the overall population presenting with rhythm and conduction disturbances in the setting of acute MI and well-preserved left ventricular function.

Despite the small patient population, acute scintigraphic indicators of MI size and relative myocardial perfusion were able, unlike other variables, to discriminate quite well between patients who survived with a benign asymptomatic course and those who died. Although atrial fibrillation is related to a poor prognosis after acute MI,[30] this relation may well be indirect. Here, atrial arrhythmias were associated with larger scintigraphic abnormalities, and MI size may be the important prognostic factor. It is likely that part of the particularly high prognostic value of the large scintigraphic abnormality provides some measure of reserve capability and relates to an expression of patient vulnerability. This parallels the work of Sharpe et al,[31] who found an inverse relation between left ventricular stroke work index and scintigraphic measured TcPYP MI size.

Since early perfusion scintigraphy and not infarct scintigraphy could best differentiate among the subgroups during the late clinical course, the prognosis of these patients is likely related not only to the size of acute infarction but also to the extent of MI-related myocardial ischemia. The ability of the scintigraphic measure of perfusion to separate prognostic subgroups supports data relating to the size of the perfusion scintigraphic defect to prognosis late after acute MI in patients presenting acutely in Killip classes 1 or 2.[13] These authors also believe that acute variables of myocardial perfusion yield the most discriminatory indexes for late prognosis since such prognosis is likely related not only to the absolute amount of infarcted myocardium but also to the quantity of related ischemic myocardium at risk. The perfusion scintigram, alone among these studies evaluated, provides such a visual assessment.[32]

Left ventricular EF may vary considerably in patients after infarction regardless of the apparent clinical level of ventricular function.[14,31,33] Scintigraphic EF has been shown to have prognostic value in studies conducted in unselected populations of patients with acute MI.[33] Here, however, the range of EF was relatively narrow and left ventricular EF measured early after the event was of little value for prognostic purposes in this select group of patients presenting without evidence of congestive heart failure. Prior assessment of percent abnormally contracting segment applied in the parent population of 62 patients showed no superior prognostic value to that of the more easily acquired counts EF.[14]

Patients who have rhythm and conduction disturbances without congestive heart failure during acute MI may follow an uncomplicated or a complicated late clinical course. This study demonstrates for the first time that early scintigraphic measurements of MI and abnormal perfusion, but not left ventricular EF, correlate with the late clinical course. This would imply that the late clinical course in these patients can be identified early after infarction from scintigraphic variables. Control of rhythm and conduction disturbances during the acute phase of MI, accomplished in all patients studied here, does not necessarily presage a good prognosis. Prognosis seems more related to the extent of acute myocardial damage, reversible or irreversible, and the extent of such damage can best be measured scintigraphically. An anterior site, transmural distribution, and occurrence of prior MI tended to relate to larger scintigraphic defects and a poor prognosis in

the larger population of 62 patients.[14] A lack of correlation between scintigraphic and enzymatic parameters may be due in part to the fact that scintigraphic defects, as evaluated herein, are area measurements, related in some cases to the extent of ischemia as well as infarction, while enzymes measure infarct density and vary with unpredictable kinetic factors.[8,29]

The size of perfusion scintigraphic abnormalities need not relate absolutely to the extent of pathologic damage and in previous studies using similar methods, such scintigraphic measures have overestimated the pathologic MI size.[10] Yet, the size of the perfusion defect was quite discriminating for prognosis when expressed as a percentage of the overall projected left ventricular myocardium. This runs parallel to pathologic studies relating the extent of myocardial necrosis to prognosis after MI,[3] and the scintigraphic percentage related to a poor prognosis appears to be in the range of 30 to 35% of left ventricular involvement on the perfusion scintigram, similar to the 40% rate quoted on pathologic study. Like the findings of others,[15,33] resting left ventricular function was of limited prognostic value in this study, largely owing to the subgroup of patients evaluated in which there were only 5 patients with a left ventricular EF <40%. While each of these 5 had congestive heart failure or died, 10 other patients with a higher EF also shared a common prognosis. However, not a single patient, asymptomatic on follow-up, had a left ventricular EF <40%. This lack of prognostic sensitivity in the presence of prognostic specificity is likely related to the fact that, while the perfusion scintigram provides a measure of both regions of ischemia and infarction, left ventricular functional assessment reflects the sum of the global functional decrement owing to these 2 variables, but modified in an unpredictable way by the state of the unaffected ventricle and the premorbid level of ventricular function. Recent work indicates the improved prognostic value of left ventricular functional variables measured on stress blood pool scintigraphy in the post-MI period.[34]

Quantitation was carried out by a manual method necessitated by the tools available at the institution of study. However, reproducibility was excellent for infarct and perfusion images. Intraobserver variations (mean ± standard deviation) were ±4% and ±6%, while interobserver variability measured ±6% and ±7%, respectively. Although new computer methods might further objectify results and add significance to our findings, other groups have shown close agreement between manual quantitative methods and objective computer methods.[10,11,13] Regardless of the method of quantitation employed, the assessment of planar scintigraphic images will always find difficulty in the case of inferior and nontransmural MI.[35]

We sought to assess the extent of MI, related perfusion, and functional abnormalities in the immediate post-MI period. This cannot always be done owing to clinical and technical factors. It has been documented that scintigraphic values, and particularly perfusion scintigraphic abnormalities, appear to improve when studied serially in many patients following acute MI.[36] Nonetheless, in the present study, scintigraphic studies, and particularly perfusion scintigraphic studies, were able to discriminate among prognostic subgroups in spite of the fact that rare studies were obtained as late as 10 days after the event. There was no significant difference in the scintigraphic defect size or related prognostic value of the scintigraphic study among these patients studied at varying intervals after symptom onset. This and previous studies suggest that the measurement of scintigraphic defect size, days after infarction, can have significant prognostic value. While quite reproducible, image measurements made here lack the full objectivity and reliability of computer methods. Nevertheless, this assessment of analog images proved valuable for the assessment of prognosis. While computer methods might enhance such objective, quantitative data and possibly add to its prognostic value, the prognostic information is apparently already present on analog images. Similarly, owing to technical advances, left ventricular EF was measured by 2 different methods during the course of this evaluation. Both methods have been shown highly accurate and reproducible by us[37,38] and others.[39] Further studies, applying yet more quantitative methods, could add prognostic value to the scintigraphic results, rendering them of further specific use. The data presented here suggest that a scintigraphic assessment of the acute infarct patient, specifically presenting with rhythm and conduction disturbances but in the absence of heart failure, could provide an accurate statistical probability of late patient prognosis. In many cases, such prognostic data could be extremely important in the consideration and implementation of patient management in the acute infarct setting and thereafter.

Differentiation Between Right and Circumflex Coronary Artery Disease on Thallium Myocardial Perfusion Scanning

HENRY N. NEWMAN, MB, BS, FRACP, RICHARD F. DUNN, MB, BS, FRACP, PHILLIP J. HARRIS, MB, BS, DPhil, FRACP, GEORGE J. BAUTOVICH, MB, BS, PhD, FRACP, ANDREW F. McLAUGHLIN, MB, BS, FRACP, and DAVID T. KELLY, MB, ChB, FRACP

Thallium defects in the inferior and lateral walls of the heart were correlated with right and circumflex coronary artery disease (CAD) in 405 patients who underwent coronary arteriography. In the 102 patients with either single right or left circumflex (LC) CAD, inferior segment defects (anterior view) were associated with right CAD, and both lateral segment defects (40° left anterior oblique view) and posteroinferior defects (60° left anterior oblique view) were associated with LC CAD. In all 405 patients, inferior segment defects had a sensitivity of 65%, a specificity of 92%, and a predictive accuracy of 89% for right CAD, and lateral segment defects had a sensitivity of 52%, a specificity of 96%, and a predictive accuracy of 90% for LC CAD. Posteroinferior defects had a low predictive accuracy for narrowing in either artery. The presence or absence of concomitant anterior defects did not alter these results. Narrowing in both right and LC coronary arteries was best identified by a combination of inferior and lateral segment defects (sensitivity 30%, specificity 96%, predictive accuracy 72%). Narrowing in only 1 of these 2 arteries was best identified by a combination of inferior segment without lateral segment defects for right CAD (sensitivity 63%, specificity 86%, predictive accuracy 55%) and lateral segment without inferior segment defects for LC CAD (sensitivity 45%, specificity 92%, predictive accuracy 57%). Thallium scanning identifies significant narrowing in the right and LC coronary arteries, and these may be separated by the pattern of defects.

Thallium-201 myocardial perfusion scanning may help both to diagnose coronary artery disease (CAD) and to localize the area of ischemia.[1–10] Thallium perfusion defects in the anterior wall of the heart strongly suggest significant narrowing of the left anterior descending coronary artery,[6–10] but defects in the inferior and lateral walls may result from obstruction in either the right or the left circumflex (LC) coronary artery.[8,10] This study examines the distribution of thallium defects within the inferior and lateral walls to predict whether the right or the LC coronary artery was obstructed.

Methods

The study group included 405 consecutive patients (364 men and 41 women) who underwent exercise thallium scanning and coronary arteriography to assess CAD. Patients with a clinical diagnosis of valvular heart disease or cardiomyopathy and patients who had previous coronary bypass surgery were excluded. The mean age of the patients was 51 years (range 27 to 70). Exercise thallium scanning was performed within 6 months of coronary arteriography in all but 12 patients, in whom arteriography preceded thallium scanning by 6 to 24 months.

Exercise thallium-201 myocardial scanning: The patients performed maximal exercise on an upright bicycle ergometer or on a treadmill using a graded multistage, continuous protocol[3] until they experienced chest pain, breathlessness, or fatigue. A 12-lead electrocardiogram was recorded before and during each minute of exercise and recovery. At peak exercise, 1.5 to 2.0 mCi of thallium-201 was injected intravenously, and the patients exercised for another minute. Scanning was begun 5 minutes after the administration of thallium-201. Four views were obtained: anterior, 40° left anterior oblique, 60° left anterior oblique, and left lateral, using a Searle PHO-Gamma mobile camera and low-energy all-purpose parallel-hole collimator, as previously described.[3]

The scans were interpreted at the time of study from the original Polaroid scintiphotographs without computer enhancement or background subtraction, by the consensus of 3 experienced observers, who had no knowledge of the patients. Each of the 4 views was diagrammatically divided into 3 segments, as shown in Figure 1, and analyzed for the presence or absence of a thallium defect. The interconsensus variability for this technique is 7%.[8]

Defects in the inferior and lateral walls (Fig. 1) were defined as defects in 1 or more of the following segments: inferior in the anterior view, lateral in the 40° left anterior

POST	42	69	29	71	NS

ANT = anterior; ANT LAT = anterolateral; ANT SEPT = anteroseptal; LAO = left anterior oblique; LAT = lateral segment; LC = left circumflex coronary artery; NS = not significant; POST = posterior; SEPT = septal.

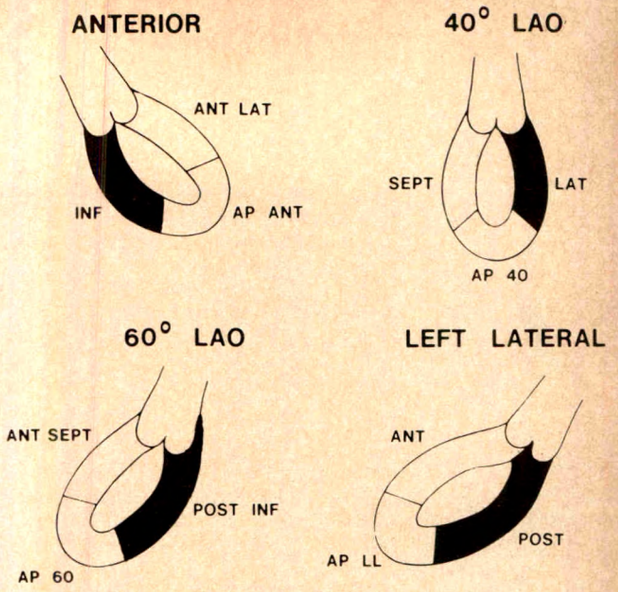

FIGURE 1. Location of inferior and lateral segments (**black**) in the 4 views of the thallium scan. ANT = anterior; ANT LAT = anterolateral; ANT SEPT = anteroseptal; AP ANT = apical, anterior view; AP LL = apical, left lateral view; AP 40 = apical, 40° LAO view; AP 60 = apical, 60° LAO view; INF = inferior segment; LAO = left anterior oblique; LAT = lateral; POST = posterior; POST INF = posteroinferior; SEPT = septal.

oblique view, posteroinferior in the 60° left anterior oblique view, and posterior in the left lateral view.[8] Anterior defects were defined as defects in 1 or more of the following segments: anterolateral in the anterior view, septal in the 40° left anterior oblique view, anteroseptal in the 60° left anterior oblique view, and anterior in the left lateral view.[8] Defects in the inferior, lateral, and anterior walls usually extended into the apical segments, which were defined as nonspecific.

Coronary arteriography: Selective coronary arteriography was performed in multiple projections using the Judkins or Sones techniques. Each study was reviewed by 2 experienced angiographers. The maximal luminal diameter narrowing for each major coronary artery was estimated visually, and mean measurements were used if the angiographers' opinions differed. Significant narrowing was defined as obstruction of at least 70% in the distribution of the left anterior descending, right, or LC coronary arteries or their major branches. All patients with left main coronary narrowing also had significant narrowing of the right coronary artery and were classified as 3-vessel disease.

Data analysis: Data were analyzed using the Yates-corrected chi-square test and the McNemar test.[11] Sensitivity was defined as the ratio of true positives to the sum of true positives and false negatives. Specificity was the ratio of true negatives to the sum of true negatives and false positives. Predictive accuracy of a positive test was the ratio of true positives to the sum of true positives and false positives.

Patients with single right and LC CAD were analyzed first to see which defect was most closely associated with narrowing in these 2 arteries. Then, all patients were analyzed to determine the predictive accuracy of defects in the inferior and lateral walls for narrowing of the right and LC coronary arteries.

Results

The distribution of CAD and the incidence of defects in the inferior and lateral walls in the 405 patients are shown in Table I.

Isolated right and left circumflex narrowing (Table II): In the 61 patients with isolated right CAD, thallium defects were most frequent in the inferior segment (77%), posterior segment (69%), and posteroinferior segment (57%). Apical defects also were frequent, whereas defects in the anterolateral, septal, anteroseptal, anterior, and lateral segments were uncommon. The typical pattern of thallium defects associated with isolated right CAD is shown in Figure 2.

When the 41 patients with isolated LC CAD were compared with patients with isolated right CAD, defects were more frequent in the lateral segment (68%, $p < 0.001$) and posteroinferior segment (83%, $p < 0.001$),

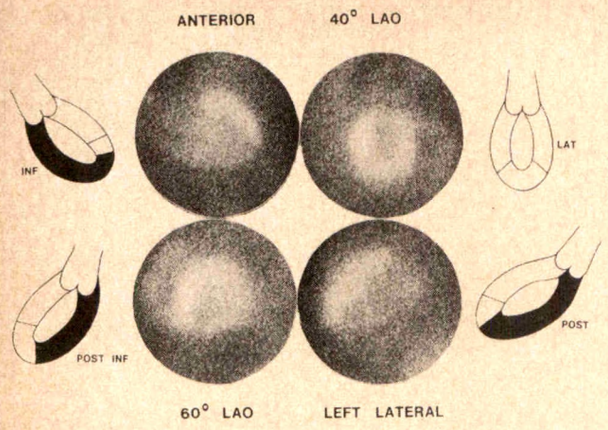

FIGURE 2. Exercise thallium scan of a patient with single-vessel right coronary artery disease. Perfusion defects are present in the inferior and apical segments in the anterior view, posteroinferior and apical segments in the 60° left anterior oblique view, and posterior and apical segments in the left lateral view, and are represented as **black areas** on the diagrams. Abbreviations as in Figure 1.

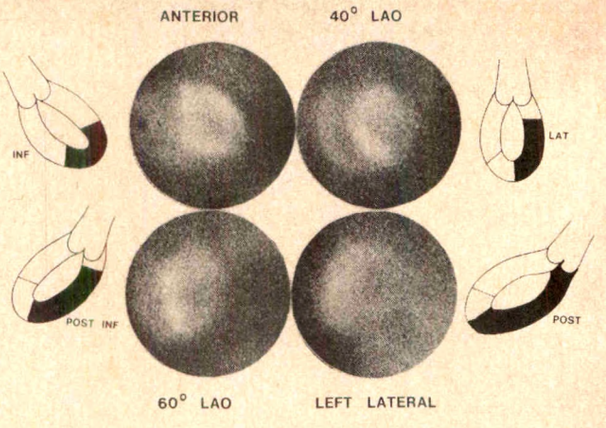

FIGURE 3. Exercise thallium scan of a patient with single-vessel left circumflex coronary artery disease. Perfusion defects are present in the apical segment in the anterior view, lateral and apical segments in the 40° left anterior oblique view, posteroinferior and apical segments in the 60° left anterior oblique view, and posterior segment in the left lateral view, and are represented as **black areas** on the diagrams. Abbreviations as in Figure 1.

and were less frequent in the inferior segment (19%, $p < 0.001$). The typical pattern of thallium defects in isolated LC CAD is shown in Figure 3. Because of the association of inferior defects with right CAD and lateral and posteroinferior defects with LC CAD, the sensitivity and specificity of these defects were examined in the total population.

Detection of right and circumflex disease (Tables III and IV): The sensitivity, specificity, and predictive accuracy of inferior, lateral, and posteroinferior defects for narrowing in right or LC coronary arteries were tested in all patients. Posteroinferior defects occurred equally in both right and LC CAD and were not analyzed further. Apical defects were not analyzed, as they can occur in patients with isolated left anterior descending, LC, and right CAD and have little localizing value.[5–9]

The relation between inferior thallium defects and right CAD is shown in Table III. Inferior defects had a sensitivity of 65% and a specificity of 92%. The predictive accuracy of inferior defects for right CAD was 89%, whereas in the absence of inferior defects there was still a 28% probability of right CAD (that is a predictive accuracy for absence of right CAD of 72%).

The relations between the lateral and posteroinferior defects and LC CAD are shown in Tables IV and V. The sensitivity of lateral defects for LC CAD was 52%, the specificity was 96%, and the predictive accuracy was 90%. Absence of lateral defects had a predictive accu-

	−	71	185	Predictive Accuracy for Absence of Right CAD $= \frac{185}{256} = 72\%$

Sensitivity $= \frac{132}{203} = 65\%$ Specificity $= \frac{185}{202} = 92\%$

TABLE IV Sensitivity, Specificity, and Predictive Accuracy of Thallium Defect in Lateral Segment (LAT) for Left Circumflex (LC) Coronary Artery Disease (CAD)

		LC CAD (n = 180) +	LC CAD (n = 180) −	
LAT Thallium Defect (n = 103)	+	93	10	Predictive Accuracy for Presence of LC CAD $= \frac{93}{103} = 90\%$
	−	87	215	Predictive Accuracy for Absence of LC CAD $= \frac{215}{302} = 71\%$

Sensitivity $= \frac{93}{180} = 52\%$ Specificity $= \frac{215}{225} = 96\%$

TABLE V Sensitivity, Specificity, and Predictive Accuracy of Thallium Defect in Posteroinferior Segment (POST INF) for Left Circumflex (LC) Coronary Artery Disease (CAD)

		LC CAD (n = 180) +	LC CAD (n = 180) −	
POST INF Thallium Defect (n = 171)	+	123	48	Predictive Accuracy for Presence of LC CAD = 123/171 = 72%
	−	57	177	Predictive Accuracy for Absence of LC CAD = 177/234 = 76%

Sensitivity = 123/180 = 68% Specificity = 177/225 = 79%

racy for absence of LC CAD of 71%. The sensitivity of posteroinferior defects for LC CAD was 68%, the specificity was 79%, and the predictive accuracy was 72%. Absence of posteroinferior defects had a predictive accuracy for absence of LC CAD of 76%.

Influence of anterior defects: The predictive accuracies of inferior, lateral, and posteroinferior defects were compared in the 158 patients with and the 247 patients without anterior defects. The predictive accuracies of inferior defects for right CAD (93 versus 87%) and lateral defects for LC CAD disease (100 versus 87%) did not differ significantly in the presence and absence of anterior defects. Posteroinferior defects more accurately predicted LC CAD in patients with anterior defects than in patients without anterior defects (90 versus 66%; $p < 0.001$).

Right and left circumflex narrowing: The pattern of defects in patients with right and LC CAD is shown in Figure 4. Unlike in patients with isolated right and LC CAD, defects commonly occurred in both inferior and lateral segments. Various combinations of these and other segments were analyzed to determine whether disease in the right, LC, or both could be differentiated.

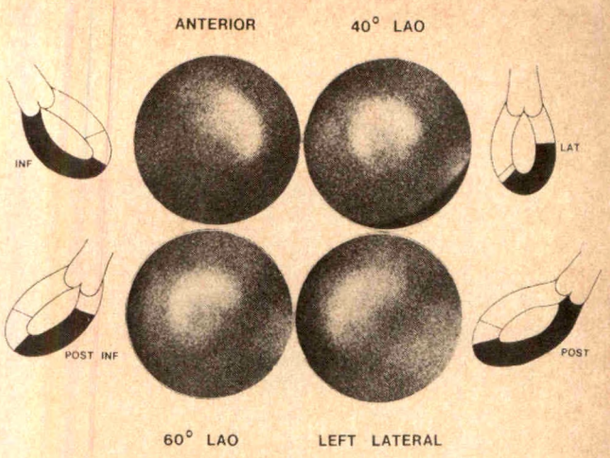

FIGURE 4. Exercise thallium scan of a patient with right and left circumflex coronary artery disease. Perfusion defects are present in the inferior segment in the anterior view, lateral segment in the 40° left anterior oblique view, posteroinferior segment in the 60° left anterior oblique view, posterior segment in the left lateral view, and in apical segments in all 4 views, and are represented as **black areas** on the diagrams. Abbreviations as in Figure 1.

The 3 combinations of defects in the inferior and lateral segments best differentiated CAD in the right, LC, and both (Table VI). Right CAD was best predicted by inferior defects without lateral defects (sensitivity 63%, specificity 86%, predictive accuracy 58%), but this combination also occurred in 32% of patients with both right and LC CAD. Left circumflex coronary artery disease was best predicted by lateral defects without inferior defects (sensitivity 45%, specificity 92%, predictive accuracy 57%), but this combination also occurred in 38% of patients with both right and LC CAD. Right and LC disease was best predicted by defects in both the inferior and lateral segments (sensitivity 30%, specificity 96%, predictive accuracy 72%).

Discussion

This study suggests that thallium defects in the inferior segment of the anterior view predict right CAD and defects in the lateral segment of the 40° left anterior oblique view predict LC CAD. Initially, we examined the pattern of thallium defects in single CAD, as in these patients the defects were related only to the diseased

single artery narrowed. Defects in the inferior segment were significantly more common in patients with right CAD and defects in the lateral and posteroinferior (60° left anterior oblique view) segments were significantly more common in patients with LC CAD. Previous studies have shown that inferior defects are common in right CAD, but too few patients with single-vessel LC CAD have been studied to determine the incidence of lateral segment defects.[6,8,9] In our study, there were 41 patients with single LC CAD; 28 (68%) had a perfusion defect in the lateral segment, whereas only 5% of patients with single right CAD had a similar defect.

After correlating scan defects in patients with single right CAD and LC CAD, defects in all 405 patients were analyzed and compared with the coronary anatomy. Inferior segment defects predicted right CAD (predictive accuracy 89%, specificity 92%). In contrast, lateral segment defects predicted LC CAD (predictive accuracy 90%, specificity 96%). Posteroinferior segment defects, although more common in LC CAD, occurred also in right CAD and did not predict either accurately.

Although defects in the inferior and lateral segments accurately predicted right and LC CAD, normal thallium uptake in these segments did not exclude narrowing of that artery. Approximately 30% of patients without inferior or lateral defects had significant narrowing of the right and LC coronary arteries. This poor predictive accuracy for the absence of significant narrowing is related to the low sensitivity of each of these segments for the presence of narrowing. Only 65% of patients with right CAD had inferior segment defects and only 52% of patients with LC CAD had lateral defects. These sensitivities are, however, similar to previous reports that have used visual interpretation of thallium scans.[6,7,10,12,13] Such interpretation does not detect narrowing in all significantly obstructed arteries.[6,7,12–14] As thallium defects represent relative abnormalities in myocardial perfusion, only the most ischemic vascular area will appear abnormal, and ischemia in another vascular territory may not be apparent. The vascular supply to a specific myocardial segment may vary in different patients, and overlap in an individual patient. Also, the severity of obstruction at angiography may be difficult to determine. Quantitative computer-assisted analysis improves interpretation.[13,14]

Perfusion defects in the inferior wall may be either underestimated or overestimated in the presence of anterior perfusion defects. Rigo et al[12] found that significant right and LC CAD may be missed if anterior defects are present, but there have been no previous studies to determine if inferior wall defects are overestimated in the presence of anterior defects. This study indicates that the predictive accuracies of inferior defects for right CAD and lateral defects for LC CAD did not significantly differ whether or not anterior defects were present. However, defects in the posteroinferior segment better predicted LC CAD when anterior defects were present and had a similar accuracy in defects in the lateral segment.

Previous studies have suggested that right CAD and LC CAD are difficult to separate on thallium scanning[8,10] because the vascular territories may vary. We found that inferior defects predicted right CAD and lateral defects predicted LC CAD; we analyzed combinations of defects to try to separate right from LC CAD. As expected, defects in the inferior without lateral defects were most common in right CAD but also occurred in 32% of patients with both right and LC CAD. Similarly, defects in the lateral without inferior defects were most common in LC CAD, but occurred in 38% of patients with CAD of both arteries. Defects in both the inferior and lateral segments occurred only occasionally in right and LC CAD and were suggestive of CAD in both.

Left Ventricular End-Systolic Pressure-Volume Relation

A Combined Radionuclide and Hemodynamic Study

ABDULMASSIH S. ISKANDRIAN, MD, A-HAMID HAKKI, MD, CHARLES E. BEMIS, MD, SALLY A. KANE, RN, BARBARA BOSTON, RN, and ANGELO AMENTA, RT

This study examines the effect of increasing heart rate by atrial pacing on the left ventricular end-systolic pressure-volume relation and determines whether peak pressure can be used instead of end-systolic pressure. Measurements were made of cardiac output (by thermodilution), pulmonary arterial pressure, ejection fraction (by radionuclide angiography), and aortic pressure (by intraarterial catheter). End-systolic pressure was measured at the dicrotic notch. The end-diastolic and end-systolic volumes were determined from the ejection fraction and cardiac output. There was excellent correlation in pressure-volume relation determined by peak pressure and end-systolic pressure ($r = 0.95$). In 8 normal subjects there was <5% change in ejection fraction, a decrease in end-systolic volume, ≥30% increase in end-systolic pressure/end-systolic volume, and no change in pulmonary arterial pressure with pacing. Of 20 patients with coronary artery disease, 9 patients had ≥5% decrease in ejection fraction, 6 had an increase in end-systolic volume, and 14 had <30% increase in end-systolic pressure/end-systolic volume with pacing ($p < 0.05$). Thus (1) peak systolic pressure can be used reliably instead of end-systolic pressure; (2) atrial pacing has a positive inotropic effect in normal subjects—the minimal increase (30%) in end-systolic pressure/end-systolic volume is similar to the increase (35%) reported during exercise; (3) abnormal changes in end-systolic pressure/end-systolic volume in coronary artery disease are more common than changes in either ejection fraction or end-systolic volume with atrial pacing.

Several studies have used radionuclide ventriculography at rest and during exercise to evaluate left ventricular (LV) function.[1–3] Atrial pacing has also frequently been used to induce myocardial ischemia.[4–17] In experimental animals, the isolated left ventricle shows a linear end-systolic pressure-volume relation that is not dependent on the preload.[18] The slope of this relation is determined by the contractile state and is increased by positive inotropic interventions.[18,19] Recently, radionuclide studies have used the pressure-volume relations as a means of assessing LV function.[1] In these studies, peak pressure was used instead of end-systolic pressure, as was originally suggested.[18] This study examines the effects of increasing heart rate by atrial pacing on the end-systolic pressure-volume relation and determines whether peak pressure can be used instead of end-systolic pressure.

Methods

The patient population consisted of 8 normal subjects and 20 patients with coronary artery disease (CAD). The normal subjects (6 men and 2 women; age range 37 to 67 years, mean 37) had normal coronary angiograms. The patients with CAD had stable angina pectoris and were found (by coronary arteriography) to have ≥70% diameter narrowing of 1 vessel (9 patients), 2 vessels (6 patients), or 3 vessels (5 patients). There were 17 men and 3 women, with an age range of 38 to 73 years (mean 55). Nitrates were withheld for at least 2 hours before the study but propranolol, which was prescribed for 12 patients, was not discontinued. There were no complications.

The pacing studies were performed with the patient in the supine position. Three catheters were inserted percutaneously with the patient under local anesthesia with lidocaine. First, a 6Fr Gorlin catheter or a 6Fr NBIH catheter was inserted by way of the left antecubital vein and positioned by means of fluoroscopy in the coronary sinus. This catheter was used for pacing. Second, a 7Fr triple-lumen balloon-tipped thermodilution catheter was inserted by way of a femoral vein and

AO = mean aortic pressure (mm Hg); C = control; CAD = coronary artery disease; CI = cardiac index (liters/min/m^2); EDVI = end-diastolic volume index (ml/m^2); EF = left ventricular ejection fraction (%); ESP/ESV = end-systolic pressure/end-systolic volume; ESVI = end-systolic volume index (ml/m^2); NS = not significant; P = pacing; P_1 = submaximal pacing; P_2 = maximal pacing; PA = mean pulmonary artery pressure (mm Hg). EDVI and ESVI were derived from the thermodilution and radionuclide angiographic measurements according to Equations 2 and 3.

advanced into the pulmonary artery. This catheter was used to measure pulmonary artery pressure and cardiac output. Third, a short (6 inch) 6Fr Teflon® catheter was inserted into a femoral artery to monitor systemic pressure. After the catheters were in position, we obtained baseline measurements of the pulmonary artery and the aortic pressures. End-systolic pressure was measured at the level of the dicrotic notch.

Pacing was then begun with gradual increments of heart rate by 10 beats/min. Pacing was continued for a minimum of 2 minutes to assure hemodynamic stability, and then the measurements were repeated. In the first 10 patients with CAD (Group I), pacing was done at 1 rate. The endpoints of pacing in these patients were the development of Wenckebach atrioventricular block, or severe angina pectoris, or at least 2 mm S-T segment depression. In the last 10 patients, pacing studies were performed at 2 different rates (Group II). During the first study, the heart rate was increased by at least 20 beats/min above the control rate; during the second pacing study, the pacing rate was determined by 1 or more of the pacing endpoints described above.

Radionuclide angiograms were obtained in the control state and during pacing. All radionuclide angiography studies were performed in the anterior projection by the first-pass method with a computerized multicrystal camera (Baird-Atomic System-77).

Radionuclide angiograms were processed to measure LV ejection fraction, end-diastolic volume, and end-systolic volume using the computer software incorporated into the Baird-Atomic System.[20,21] The reliability and reproducibility of the method have been previously reported.[2,3,20] The LV end-diastolic volume and end-systolic volume were derived as follows by an independent method using the cardiac output determined by the thermodilution method, and the ejection fraction determined by the radionuclide angiogram: Stroke volume (milliliters by thermodilution) = cardiac output (milliliters/minute by thermodilution)/heart rate (beats/minute) (Equation 1). This stroke volume was then used in the next 2 equations: End-diastolic volume (milliliters) = stroke volume (milliliters)/ejection fraction (%) (Equation 2); and End-systolic volume (milliliters) = end-diastolic volume (milliliters) − stroke volume (milliliters) (Equation 3).

Statistical analysis: The results are expressed as mean ± standard deviation (SD) when appropriate. Differences between the rest and pacing studies were analyzed by the paired *t* test or analysis of variance. Comparison of volume measurements by different methods was performed by linear correlation analysis.

Results

Clinical, electrocardiographic, and hemodynamic changes during pacing: No normal subject had angina or S-T depression during pacing. In 11 patients (55%) with CAD, angina or S-T depression (or both) developed during pacing. The hemodynamic data in normal subjects and in patients with CAD at rest and during pacing are shown in Table I.

Changes in ventricular function and volumes during pacing: In normal subjects, there were significant decreases in end-diastolic and end-systolic volumes during pacing (Fig. 1 and 2), while the change in the ejection fraction was 0 to 4% (Fig. 3). In the 10 patients with CAD who had 1 pacing study (Group I), 2 patients had ≥5% decrease in ejection fraction with pacing while among the remaining 10 patients who had studies at 2 pacing rates (Group II), 8 patients showed ≥5% decrease in the ejection fraction at the final pacing rate compared

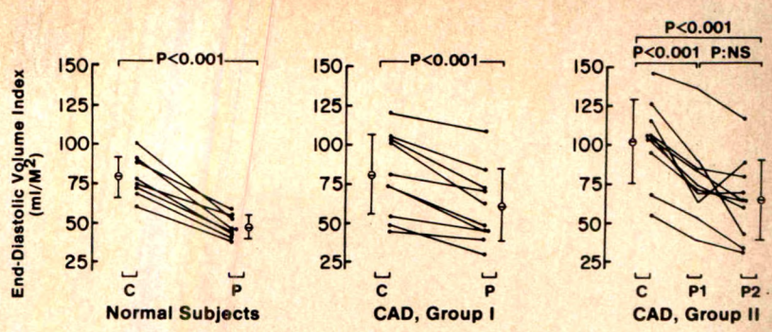

FIGURE 1. Changes in end-diastolic volume index during pacing in normal subjects and patients with coronary artery disease. C = control; CAD = coronary artery disease; P = pacing. Means ± standard deviations are shown.

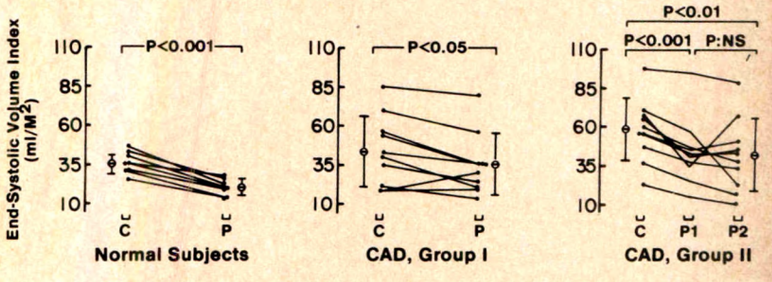

FIGURE 2. Changes in end-systolic volume index during pacing. C = control; CAD = coronary artery disease; P = pacing. Means ± standard deviations are shown.

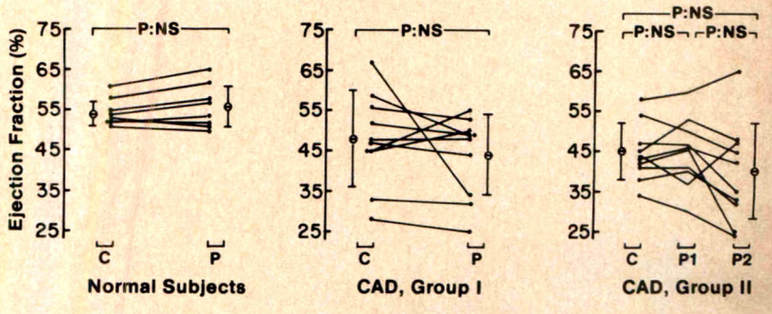

FIGURE 3. Changes in ejection fraction during pacing. C = control; CAD = coronary artery disease; P = pacing. Means ± standard deviations are shown.

with measurements at the first pacing rate (Fig. 3). The end-systolic volume increased during pacing in 2 patients in Group I and in 4 patients in Group II (Fig. 2). The end-diastolic volume decreased during pacing in both groups (Fig. 1). The end-systolic pressure-volume relation was determined in the normal subjects and in patients with CAD by using either peak systolic pressure or end-systolic pressure. The correlation between peak pressure-to-end-systolic volume ratio and the end-systolic pressure-to-end-systolic volume ratio was excellent ($r = 0.95$) (Fig. 4). The end-systolic pressure to end-systolic volume ratio increased by ≥30% in normal subjects. On the other hand, 6 patients with CAD in Group I and 8 patients in Group II had <30% increase (Fig. 5). An abnormal increase in the end-systolic pressure/end-systolic volume ratio was more common than an abnormal response to the ejection fraction or an increase in end-systolic volume during pacing (70% versus 50% versus 30%, respectively) ($p < 0.05$, change in end-systolic pressure to volume ratio compared with increase in end-systolic volume).

An abnormal response of the ejection fraction to pacing was found in 4 of 9 patients with 1-vessel disease and in 5 of 11 patients with multivessel disease (p = not significant [NS]). An abnormal change in end-systolic pressure-to-end-systolic volume ratio was found in 4 of 9 patients with 1-vessel disease and in 10 of 11 patients with multivessel disease ($p < 0.05$). In evaluating the results in relation to resting LV function, an abnormal ejection fraction response was noted in 3 of 6 patients with normal function and in 6 of 14 patients with abnormal function, and abnormal pressure-volume relation was noted in 4 of 6 patients with normal function and in 10 of 14 patients with abnormal function (p = NS).

An abnormal response in ejection fraction was noted in 3 of 8 patients not receiving propranolol therapy and in 6 of 12 patients receiving propranolol therapy (p = NS), and an abnormal change in pressure-volume relation was noted in 5 patients not receiving propranolol therapy and in 9 patients receiving such therapy (p = NS).

The mean normalized systolic ejection rate (ejection fraction/ejection time) decreased in the normal subjects (0.32 ± 0.03 control versus 0.26 ± 0.02 s^{-1} pacing, <0.001), but increased in patients with CAD (1.51

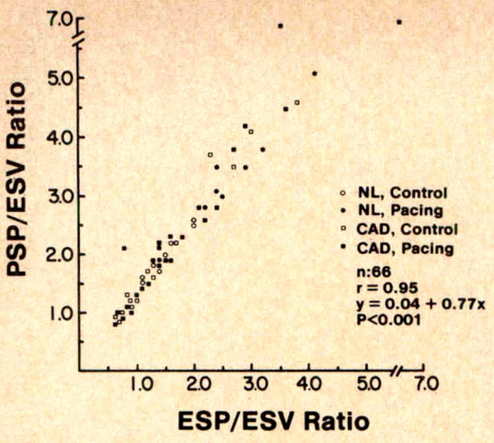

FIGURE 4. Correlation between the peak systolic pressure to end-systolic volume (PSP/ESV) ratio and the end-systolic pressure to end-systolic volume (ESP/ESV) ratio. CAD = patients with coronary artery disease.

0.38 control versus 1.69 ± 0.47 s^{-1} pacing, $p < 0.05$). All 8 normal subjects had a decrease while 14 of 20 patients with CAD had an increase ($p < 0.02$).

Finally, we found a good correlation between radionuclide derived end-diastolic and end-systolic LV volumes and similar volumes determined from thermodilution stroke volume and radionuclide ejection fraction (Equations 2 and 3) (Table II).

Discussion

We evaluated ventricular function by means of atrial pacing in normal subjects and in patients with CAD. We measured LV volumes by 2 methods: first, by radionuclide angiography, and second, by using the stroke volume derived from the thermodilution cardiac output and the ejection fraction derived from the radionuclide angiogram. This second method is not entirely independent from the first, but it is based on data derived by 2 reliable methods. This report, therefore, combines the best available methods for accurate measurement of ventricular volumes and has advantage over volume measurement by contrast angiography, since segmental wall-motion abnormalities during ischemia and changes in the shape of the ventricle may affect the reliability of geometric methods for volume measurements. In a

ESV (using Equation 3) = 18 + 0.74 × ESV (by RNA), r = 0.85

EDV = end-diastolic volume (milliliters); ESV = end-systolic volume (milliliters); RNA = radionuclide angiography.

landmark study, Dwyer,[5] cognizant of this problem, obtained the ejection fraction from the end-diastolic volume measured by contrast angiography and the stroke volume measured by the dye dilution method. Ten patients with CAD were studied by pacing. Dwyer found that end-diastolic volume decreased in 9 patients and the ejection fraction decreased in 8 patients.

Other investigators have similarly shown a decrease in ejection fraction during pacing-induced ischemia.[6,15,16]

Our results showed that atrial pacing resulted in a significant decrease in end-diastolic volume in patients with CAD (Table I, Fig. 1). The decrease in end-diastolic volume was a continuous one, as demonstrated in 10 patients who had measurements at 2 pacing rates. In some patients there was a marked elevation in pulmonary artery pressure despite a decrease in end-diastolic volume during pacing-induced ischemia, indicating an alteration in LV compliance as reported by other investigators.[22,23]

Our results in normal subjects showed no significant change in the ejection fraction despite a decrease in end-diastolic volume during pacing (Fig. 1 and 3). The end-systolic pressure-to-end-systolic volume ratio increased in all. These results may suggest increased inotropicity with pacing, and therefore they support the findings of other investigators.[17,24–26] There was excellent correlation between peak systolic pressure-to-end-systolic volume ratio and the end-systolic pressure-to-end-systolic volume ratio (r = 0.95) (Fig. 4), thus indicating that the peak pressure can be used reliably instead of the end-systolic pressure. Although the dicrotic pressure and the end-systolic pressure are not identical, they are usually very similar.[27] We also found

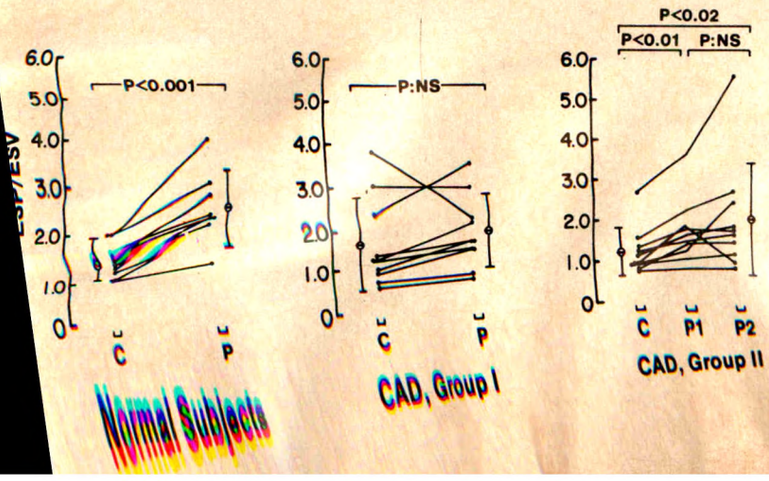

FIGURE 5. Changes in end-systolic pressure to end-systolic volume (ESP/ESV) ratio during pacing. C = control; CAD = coronary artery disease; P = pacing. Means ± standard deviations are shown.

that LV end-diastolic and end-systolic volumes can be reliably measured noninvasively by radionuclide angiography not only at rest but also during pacing-induced ischemia. These findings are important since the LV end-systolic pressure-volume relation can be determined by noninvasive measurements of the peak systemic pressure (by the cuff method) and the end-systolic volume (by radionuclide angiography). The minimal increase (30%) in the end-systolic pressure-to-end-systolic volume ratio in the normal subjects during pacing is similar to the minimal increase (35%) reported during exercise.[1]

Finally, an abnormal increase in end-systolic pressure-to-end-systolic volume ratio was seen in 14 patients (70%) with CAD, while only 6 patients (30%) had an increase in end-systolic volume ($p < 0.05$) and 10 patients (50%) had $\geq 5\%$ decrease in the ejection fraction with pacing. The normal subjects had a decrease in the mean normalized systolic ejection rate with pacing while patients with CAD had an increase. Since most patients had abnormal resting ejection fractions, the pacing studies were not done to diagnose CAD but rather to evaluate the pressure-volume changes.

Thus, peak pressure can be used reliably instead of end-systolic pressure; pacing has a positive inotropic effect in normal subjects; the minimal increase (30%) in end-systolic pressure-to-end-systolic volume ratio is similar to the increase (35%) reported during exercise; and abnormal changes in end-systolic pressure-volume relation are more frequent than changes in the ejection fraction or end-systolic volume during pacing.

Comparison of Slow-Release Pindolol, Standard Pindolol, And Propranolol in Angina Pectoris

JOHN O. PARKER, MD

Twenty-two patients with chronic, stable, exercise-induced angina pectoris were assessed during periods of therapy with propranolol, standard-formulation pindolol, and a slow-release preparation of pindolol. Patients maintained diaries of the frequency of angina pectoris and nitroglycerin consumption and underwent treadmill exercise testing at 2 weekly intervals. No significant differences were observed in nitroglycerin consumption or anginal frequency during these 3 treatment programs. Resting heart rates were higher with pindolol than with propranolol, but no differences were noted between periods on standard and slow-release pindolol. Systolic and diastolic blood pressures were similar during therapy with these 3 treatment programs. Treadmill walking time to the development of moderate angina and systolic and diastolic blood pressure was similar during treatment with propranolol, standard-formulation pindolol, and slow-release pindolol. Exercise heart rates were slightly higher during therapy with slow-release pindolol than during standard-formulation pindolol. It is concluded that propranolol, pindolol, and slow-release pindolol are equally effective in the management of patients with chronic, stable, exercise-induced angina.

The beta adrenoreceptor blocking agent, pindolol, has been effective in the management of patients with stable exercise-induced angina pectoris.[1,2] Pindolol is a nonselective beta-blocking agent that possesses the strongest partial agonist activity of any of the currently available drugs with the property. Beta-blocking drugs with this intrinsic sympathomimetic activity (ISA) have potential advantages over agents lacking this property in that there is less depression of heart rate[2,3] and there may be protection against cardiac failure[4] and bronchial asthma.[5] The plasma half-life of pindolol is similar to that of propranolol, but the drug has been shown to be effective for longer periods.[6,7] Pindolol also differs from propranolol and most other beta-blocking drugs in that it undergoes less first-pass metabolism in the liver.[8]

A slow-release form of pindolol has been developed, and preliminary data obtained at rest and during exercise have shown this to have a prolonged duration of action.[9] These data suggest that the slow-release preparation would be effective in patients with angina pectoris when administered in a single daily dose.

From the Department of Medicine, Queen's University, Kingston, Ontario, Canada. Manuscript received September 27, 1982; revised manuscript received December 24, 1982, accepted January 4, 1983.

The present investigation was designed to compare the antianginal efficacy of slow-release pindolol given once daily with standard pindolol administered twice daily in patients with stable angina pectoris. The study also permitted a comparison between the effects of these 2 preparations of pindolol and standard propranolol administered 4 times daily.

Patients: Twenty-two male patients aged 44 to 70 years (mean 57.2) with chronic, stable angina pectoris participated in this investigation. The diagnosis of coronary artery disease was confirmed either by documentation of clinical and electrocardiographic evidence of previous myocardial infarction (7 patients) or demonstration of significant coronary artery disease by selective coronary angiography (21 patients). All patients gave an unequivocal history of exertional angina pectoris despite therapy, and all had positive exercise tests with angina during exercise and horizontal depression of the S-T segments of >1 mm for at least 80 ms after the J point. No patients had clinical evidence of abnormal left ventricular function or had previously been in heart failure.

All patients had been taking standard propranolol for at least 1 month before this investigation. Twenty-one patients were taking propranolol, 40 mg 4 times daily at 8 A.M., 1 P.M., 6 P.M., and midnight, and 1 patient, 40 mg twice daily at 8 A.M. and 8 P.M. All 22 patients were considered propranolol responders and 12 patients had

such improvement documented by treadmill exercise testing before and after initiation of therapy with propranolol. In these patients, exercise time to the development of moderate angina was prolonged by at least 60 seconds when examined 4 hours after a dose of propranolol. Nine of the 22 patients were taking oral nitrates, and these were continued throughout the investigation. Patients were taking nitroglycerin to treat episodes of chest pain, but none of the patients were using sublingual nitroglycerin in a prophylactic fashion. Informed, written consent was obtained from each subject.

Methods

Study design: Each patient had been on propranolol for at least 1 month and was familiar with treadmill exercise testing. Patients taking oral nitrate preparations continued on the same dose throughout this investigation. On the initial study day, patients were instructed to report to the laboratory after an overnight fast without taking their morning medications. Blood pressure and heart rate were recorded in the supine and upright postures, and a 12-lead electrocardiogram was obtained. At 8 A.M., the patients carried out a treadmill exercise test employing Bruce's protocol.[10] Patients were asked to indicate the time when angina pectoris first developed (P_1) and were encouraged to continue to exercise to the point where the angina pectoris became of moderate severity (P_2), at which time exercise was stopped. During the exercise period, modified lead V_5 was monitored and records were taken at 1-minute intervals during exercise and during a 5-minute recovery period for the determination of heart rate and the extent of S-T segment changes. Blood pressure was recorded by sphygmomanometry at the end of each 3-minute exercise stage, at P_1 and P_2, and at 1, 3, and 5 minutes of recovery. The time from the cessation of exercise to the disappearance of angina pectoris was also recorded.

After this study, the patients were randomized into 2 groups and entered a double blind cross-over study with standard pindolol and slow release pindolol employing the same total daily dose. The study design was as follows: *Group I (11 patients)*: study period (weeks 1 to 4): 8 A.M., slow release pindolol 20 mg plus pindolol placebo, and 8 P.M., pindolol placebo; study period (weeks 5 to 8): 8 A.M., standard pindolol 10 mg plus slow release pindolol placebo, and 8 P.M., standard pindolol 10 mg. *Group II (11 patients)*: These patients received active and placebo medications in the reverse order for the 2 study periods.

Patients were seen at 2 weekly intervals and were provided with a supply of medications and diaries to maintain a record of the frequency of anginal episodes and their nitroglycerin consumption. Patients came for assessment after 2, 4, 6, and 8 weeks on these treatment regimens. At these times, patients presented in the fasting stage without taking their morning medications and were asked not to smoke. Patients on oral nitrates did not take them on the morning of these studies and none of the patients took sublingual nitroglycerin within 2 hours of assessment.

Patients were assessed on each visit and their anginal diary and nitroglycerin consumption reviewed. The medication bottles were returned and a pill count done to assess compliance. Treadmill exercise test was carried out as just described.

After the 8-week period of these pindolol treatment regimes, the patients were returned to their previous therapy with propranolol. Patients continued to record anginal episodes and nitroglycerin consumption and after 2 weeks were assessed and underwent treadmill exercise testing.

Statistical analyses were performed by employing a Latin square design for comparisons of the 2 forms of pindolol. P values ≤ 0.05 are considered significant by this method. When comparisons were made between the propranolol and pindolol phases, the Bonferroni method for analysis of variance for repeated measurements was used.[11] P values ≤ 0.01 are considered significant with this method.

Results

All 22 patients completed this study. No significant side effects were reported when drug therapy was changed from propranolol to either formulation of pindolol or when the propranolol was reinstituted for the final 2 weeks of the study.

Resting hemodynamics (Table I): Values for heart rate and systolic and diastolic blood pressure in the supine and upright positions are shown for Groups I and II in Table I. Data are shown for the initial propranolol period, during therapy with standard and slow release pindolol, and during the final phase of therapy with propranolol. Heart rate was similar in the 2 groups during both periods on propranolol and was similar in the supine and upright postures. When patients were given pindolol, resting heart rate increased significantly in both the supine and upright postures ($p < 0.01$). No significant differences in heart rate were evident between the treatment periods and the 2 formulations of pindolol. Systolic and diastolic blood pressure was similar in both groups during each phase of the investigation with propranolol and with both forms of pindolol.

Frequency of angina pectoris (Table II): During the initial propranolol phase, patients in Group I and Group II experienced an average frequency of angina pectoris of 7.6 ± 1.8 (standard error of the mean) and 9.6 ± 3.3 episodes during a 2-week period. The difference between the 2 groups was not significant. There was a gradual decrease in the frequency of angina pectoris during the period of this investigation in both groups. These changes, which may have been due to a training effect, were not significant and the frequency of angina between the groups and within the groups was similar during both the propranolol and the pindolol phases of this study.

Nitroglycerin consumption (Table II): During the initial propranolol phase, patients in Group I and Group II consumed an average of 6.7 ± 3.2 and 8.5 ± 4.0 nitroglycerin tablets in a 2-week period. The difference between the 2 groups was not significant. As with the frequency of angina pectoris, there was a gradual reduction in nitroglycerin consumption over the period of this investigation. These changes were not significant, and thus, over the period of the study, nitroglycerin consumption between the groups and within the groups was similar during both the propranolol and the pindolol phases.

Exercise testing (Table II): Treadmill walking time to the onset of angina pectoris (P_1) was similar in Group I (4.8 ± 0.4 minutes) and Group II (3.9 ± 9.4 minutes) during the initial propranolol phase. The time to moderate angina (P_2) was also similar in the 2 groups: 7.0 ± 0.3 and 6.2 ± 0.4 minutes, respectively.

* $p < 0.01$, comparison of values during pindolol and propranolol therapy by the Bonferroni method.
DBP = diastolic blood pressure; HR = heart rate; Prop = propranolol; SBP = systolic blood pressure; SF Pind = standard-formulation pindolol; SR Pind = slow-release pindolol.
Data shown are mean ± standard error.

When the patients in Group I were changed from propranolol to slow-release pindolol, treadmill walking time to P_1 was increased to 5.5 ± 0.4 minutes, a small but significant change ($p < 0.01$). Time to P_2 was also increased, being 8.0 ± 0.6 minutes, but this was not statistically significant. When these patients subsequently were changed to standard formulation pindolol, exercise time to P_1 and P_2 showed no further change and remained at approximately the same levels when the patients were changed back to propranolol for the final 2 weeks.

In Group II, the treadmill walking time to P_1 and P_2 showed no change from the initial propranolol phase to the phase with standard pindolol. When subsequently

placed on sustained release pindolol, the time to P_1 (4.9 ± 0.3 minutes) was significantly greater than that with standard pindolol (4.0 ± 0.3 min) ($p < 0.04$). However, no significant change was noted in time to P_2 during the various phases of the study in this group of patients. The time taken for angina to disappear after cessation of exercise was similar in all phases of the study.

The exercise heart rate during the 2 propranolol phases was similar. In both groups, the heart rates at the time of moderate angina during both slow release and standard formulation pindolol phases were similar to those during therapy with propranolol. Using Latin square design analyses during the 2 pindolol phases, there were small, but significant differences in heart rate at P_1 and P_2 with higher values of heart rate during the slow release phase than with the standard formulation phase.

Systolic and diastolic blood pressure was similar in Group I and Group II at both P_1 and P_2 during each phase of this investigation. S-T segments at rest and at P_1 and P_2 were similar in both groups at each phase of the study.

Discussion

Beta adrenoreceptor drugs are effective in the prophylactic management of patients with stable angina pectoris due to atherosclerotic heart disease. The therapeutic efficacy of this group of drugs is considered to be due to a decrease in left ventricular oxygen requirements secondary to reduced heart rate, systolic blood pressure, and myocardial contractility.[12] However, the slower heart rate and decreased contractility lead to increased left ventricular volume which tends to increase wall tension for any given blood pressure and may augment myocardial oxygen requirements.[13]

The beta adrenoreceptor drugs currently available for clinical use differ in some of their ancillary properties which may impact on their clinical usefulness. These properties include cardioselectivity, when agents block primarily $beta_1$ receptors, and the presence of ISA. Cardioselectivity is potentially advantageous when managing patients with reactive airway disease or patients with peripheral vascular disease in whom the absence of $beta_2$ blockade may lead to less bronchospasm and a smaller decline in muscle blood flow. Unfortunately, however, this cardioselectivity is most apparent at low concentrations, and with the doses commonly required to treat patients with angina pectoris and hypertension, cardioselectivity may be lost.[14]

The presence of ISA has potential benefits in patient management as beta-blocking drugs possessing this property have less effect on heart rate.[2,3] The presence of this partial agonist activity also may be important in maintenance of cardiac output both at rest and during exercise.[4] Thus, patients with resting bradycardia may be able to tolerate a beta-blocking drug with ISA better than a drug without this property.[4,5] It has also been suggested that patients with poor left ventricular function, obstructive airway disease, and peripheral vascular disease may tolerate this group of drugs better than drugs such as propranolol which do not have this property. There is also suggestive evidence that drugs possessing partial agonist activity may be associated with a lower incidence of fatigue than other beta-blocking drugs.[2]

Pindolol is a beta-blocking drug that is noncardioselective, but that has potent ISA, whereas propranolol, which is also noncardioselective, has no partial agonist activity. The present investigation was designed to compare the efficacy of a slow release form of pindolol with standard pindolol and to compare each of these formulations with standard propranolol. The comparison between the 2 types of pindolol was double-blind in nature and cross-over in design, whereas the propranolol phases of the investigation were open. Despite the limitations of the study design, the availability of objective data at rest and during exercise during the initial and final phases of the study while patients were receiving propranolol does provide useful comparative data regarding propranolol and the 2 formulations of pindolol.

This study did not attempt to assess the efficacy of these treatment programs on treadmill exercise tolerance throughout a 24-hour period. The timing of the exercise testing was such that each regimen was assessed at a time when the drug effects would be expected to be at a minimum. It is recognized that the clinical effects of both pindolol and propranolol are much longer in duration than would be suggested by their elimination half-lives. Thus, propranolol given twice daily has been as effective as 4 times daily therapy,[15] and treadmill exercise time to angina is prolonged for 8 to 12 hours after dosing.[16] In this study, the morning exercise test was carried out 8 hours after the last dose of propranolol, and exercise tolerance was similar to that seen 12 hours after standard formulation pindolol and 24 hours after slow-release pindolol.

Recordings of the frequency of angina pectoris and nitroglycerin consumption are of only limited value. In patients with stable angina pectoris, these variables vary directly with patient activities and in themselves are of little use in assessing clinical efficacy. Despite these reservations, this study showed similar anginal frequency and nitroglycerin consumption during the 2 pindolol phases, which in turn were similar to the periods of propranolol consumption. However, throughout the study period, there was a gradual diminution in the frequency of angina pectoris and also in nitroglycerin consumption, changes that are probably related to a training effect.

Hemodynamics at rest were similar during the 2 propranolol periods in both groups of patients. During pindolol therapy, the resting heart rates were significantly higher in both the slow release and the standard formulation phase of the investigation, reflecting the partial agonist activity of pindolol with resting heart rates increasing by approximately 10 beats/min over those levels recorded on propranolol. The resting heart rates were slightly higher after 4 weeks of therapy with slow-release pindolol than with standard formulation pindolol, but these differences were not statistically significant. Systolic and diastolic blood pressure was similar when patients were taking propranolol and both formulations of pindolol.

Exercise testing showed no major differences between propranolol and the 2 formulations of pindolol. Group I showed an increase in exercise time to the onset of angina when placed on slow-release pindolol. There was no change when subsequently given standard pindolol and propranolol and so this apparent improvement may be due to a training effect. However, there was no change in exercise time to the endpoint of moderate angina. Group II patients showed a small but significantly longer exercise time to the onset of angina while on slow-release pindolol than on standard pindolol. However, exercise times to the endpoint of moderate angina were similar while on these 3 regimens. While heart rates at rest were higher on pindolol than on propranolol, the exercise heart rate at the time of the development of moderate angina was similar during these treatment periods. Other investigators have suggested that during comparable levels of physical activity, the exercise heart rate is higher during pindolol therapy than during propranolol therapy.[2] The present study showed somewhat higher heart rates at the onset of angina when the patients were receiving slow-release pindolol than when receiving propranolol. However, no differences were seen when standard pindolol was given.

The partial agonist activity could have deleterious effects in patients with angina pectoris. The greater resting heart rate could lead to greater myocardial oxygen consumption, but the resting heart rate during pindolol therapy is usually similar to or less than that seen before initiation of therapy. The fact that the exercise heart rate was similar with pindolol and propranolol suggests that this property has little influence on heart rate during maximal exercise; other factors clearly are playing a major role in determining the heart rate response. Similarly, the presence of ISA may result in less depression of cardiac contractility and so blunt 1 of the beneficial influences of the adrenoreceptor agents. This may be the case at rest, but during exercise this factor appears to play only an insignificant role as exercise times were similar during therapy with propranolol and pindolol.

In many patients, symptomatic bradycardia develops with propranolol and similar beta-blocking drugs and may produce symptoms and be partly responsible for weakness, ease of fatigue, lassitude, and postural hypotension. These untoward effects may limit dosages so that therapeutic endpoints cannot be achieved. A drug possessing partial agonist activity is superior in this group of patients as the resting heart rate may be maintained at a higher level without these side effects.

In conclusion, this investigation indicates that patients with stable angina pectoris show a similar frequency of angina, nitroglycerin consumption, and exercise time to moderate angina when taking propranolol, standard formulation pindolol, and slow-release pindolol. The resting heart rate is higher with both forms of pindolol than with propranolol, although exercise values for heart rate at moderate angina are similar with propranolol and the 2 formulations of pindolol.

ISOPTIN® (verapamil HCl/Knoll) TABLETS OR NIFEDIPINE?

Given these facts, which would you choose?

In angina of effort, Isoptin "...was more effective and better tolerated than nifedipine..."

B Subramanian, et al, *Am J Cardiol*, 1982[1]

In angina of effort, Isoptin and nifedipine "...were equally effective...but side effects were more common with nifedipine."

JR Dawson, et al, *Br Heart J*, 1981[2]

In angina at rest, Isoptin and nifedipine "...are of similar efficacy...However, adverse effects occurred more frequently with nifedipine..."

MD Winniford, et al, *Am J Cardiol*, 1982[3]

Please see last page of this advertisement for brief summary of prescribing information.

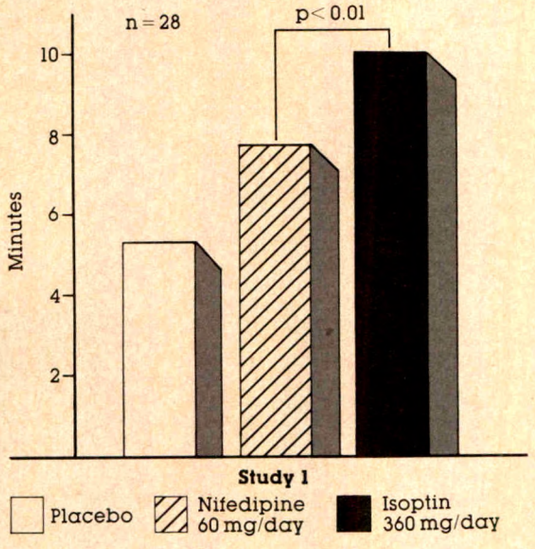
ISOPTIN® (verapamil HCl/Knoll) TABLETS OR NIFEDIPINE?

Over 20 years and 18 million patient years of experience make Isoptin the most thoroughly studied of the calcium channel blockers. Is it any wonder that Isoptin — not nifedipine or diltiazem — is indicated for first-line therapy of all forms of angina pectoris?

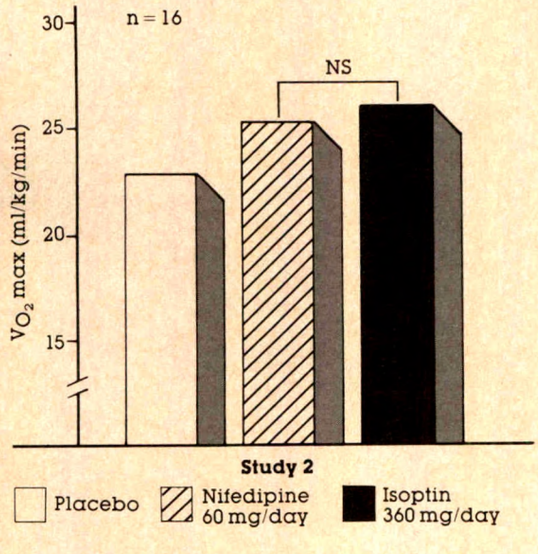
Before making your choice, consider the following clinical results. And consider the long history of safety and efficacy that makes Isoptin one of the most widely prescribed calcium channel blockers in the world.

Isoptin was equal or superior in efficacy in angina of effort

Mean Maximal Exercise Time
ISOPTIN MORE EFFECTIVE[1]

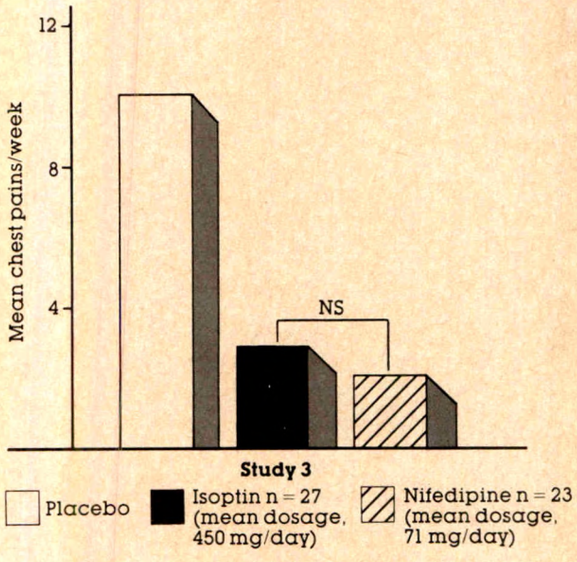


Mean Maximal Work Capacity
ISOPTIN AS EFFECTIVE[2]



Isoptin was equal in efficacy in angina at rest

Angina Frequency
ISOPTIN AS EFFECTIVE[3]



In all forms of angina, Isoptin caused fewer side effects

Study 1: "Few adverse reactions were noted with verapamil (Isoptin); none were serious, and none required discontinuation ... In contrast, 7 of the 32 patients developed side effects during nifedipine therapy serious enough to require its withdrawal..."[1]

Study 2: "...side effects with nifedipine occur frequently...In contrast, verapamil (Isoptin) was relatively free from side effects apart from constipation..."[2]

Study 3: "...adverse reactions limited the amount of nifedipine that could be administered; in contrast, side effects during verapamil (Isoptin) administration were relatively minor and did not alter the dosage."[3]

Please see next page for brief summary of prescribing information.

2090

Isoptin is contraindicated in severe left ventricular dysfunction, hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), and second- or third-degree AV block.

ISOPTIN®

(verapamil HCl/Knoll)
80 mg/120 mg Tablets

The choice becomes easier, once you have the facts.

ISOPTIN® TABLETS
(verapamil HCl/Knoll)

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure <90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** ISOPTIN should be avoided in patients with severe left ventricular dysfunction (e.g., ejection fraction <30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before ISOPTIN is used. ISOPTIN may occasionally produce hypotension (usually asymptomatic, orthostatic, mild, and controlled by decrease in ISOPTIN dose). Occasional elevations of liver enzymes have been reported; patients receiving ISOPTIN should have liver enzymes monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (e.g., W-P-W or L-G-L syndromes) may develop a very rapid ventricular response after receiving ISOPTIN (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema, and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with ISOPTIN. **Precautions:** ISOPTIN should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function, and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of ISOPTIN and beta blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, ISOPTIN should be used alone, if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with ISOPTIN and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic ISOPTIN treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when ISOPTIN is given, and the patient carefully monitored. ISOPTIN may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after ISOPTIN administration. Until further data are obtained, combined ISOPTIN and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. *Pregnancy Category C* : There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during ISOPTIN use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5%, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, maculae, and spotty menstruation. Overall continuation rate of 94.5% in 1,166 patients. **How Supplied:** ISOPTIN (verapamil HCl) is supplied in 80 mg and 120 mg sugar-coated tablets.

Frequency and Importance of Unprovoked Coronary Spasm In Patients With Angina Pectoris Undergoing Percutaneous Transluminal Coronary Angioplasty

LAMBERTO G. BENTIVOGLIO, MD, LOUIS R. LEO, MD, NELSON M. WOLF, MD, and STEVEN G. MEISTER, MD

Coronary spasm superimposed on fixed coronary artery stenosis was discovered in 14 of 74 candidates for percutaneous transluminal coronary angioplasty (PTCA). In 3 of the 14, spasm developed during PTCA and was presumably catheter-induced. Eleven of the 14, with unprovoked spasm, are the subject of this study. Three of the 11, in whom the fixed component of the mixed stenosis was subcritical, were treated medically, with good results in 2 but with persistent angina pectoris and eventual myocardial infarct in 1. Nitroglycerin administered by the intracoronary route relieved spasm resistant to sublingual nitroglycerin in 1 of the 3. In 8 of the 11 with critical fixed stenosis, spasm was discovered either before PTCA (7 patients) or on follow-up (1 patient). Six of the 8 had successful PTCA, with no or mild symptoms on follow-up. Of the 2 failures, 1, uncomplicated, was followed by successful elective coronary artery bypass surgery while the other, complicated, led to successful emergency coronary artery bypass surgery, with disappearance of symptoms in both. The rate of success was similar in patients with documented unprovoked spasm (6 of 8) and patients without (39 of 63, 62%). It is concluded that (1) coronary spasm, if properly sought for, is probably not uncommon in single-vessel candidates for PTCA; (2) patients considered candidates for PTCA should have intracoronary nitroglycerin administered before PTCA; (3) in patients with critical, fixed coronary artery disease, associated spasm does not reduce the chances of successful PTCA; (4) coronary spasm may outlast the relief by PTCA of the fixed component of the mixed stenosis and requires long-term vasodilator therapy; and (5) the lack of adverse effects when PTCA is performed in patients with spasm superimposed on critical fixed single-vessel stenosis appears to justify its use for the time being.

The existence of vasospastic angina pectoris is well established.[1,2] Coronary spasm may occur at a site with no detectable fixed stenosis or may coexist with any degree of fixed obstruction.[3]

In the context of percutaneous transluminal coronary angioplasty (PCTA), coronary spasm occupies a position of particular interest for 3 main reasons: (1) by location, focal character, and symmetry it mimics the very type of fixed coronary stenosis considered ideal for PTCA; (2) being unpredictable, it may occur during PTCA and possibly affect its immediate results; (3) being recurrent, it can be expected to outlast relief of the fixed component of a mixed stenosis, reproducing blockage and symptoms at a later time. The practical importance of these issues would be marginal if coronary spasm were rare in candidates for PTCA. However, our previous experience suggested that coronary spasm is easily overlooked and might be common in patients with isolated single-vessel stenosis. If spasm were in fact common among candidates for PTCA, it would be of considerable interest to discover the possible reasons for this common association.

A prospective study was designed to achieve the following goals: (1) to unmask spontaneous coronary spasm, when present during diagnostic angiography, in potential candidates for PTCA and establish its prevalence in patients with single-vessel disease deemed amenable to coronary angioplasty; (2) to discover to what extent this prevalence may result from the special composition of the PTCA population; (3) to determine the influence of coronary spasm on the immediate re-

From the Division of Cardiology, The Medical College of Pennsylvania and Hospital, Philadelphia, Pennsylvania. Manuscript received August 3, 1982; revised manuscript received December 10, 1982, accepted December 13, 1982.

sults and complications of PTCA; (4) to observe the possible long-term effect of coronary spasm associated with critical, fixed stenosis in patients successfully treated with PTCA.

Methods

The following protocol was established for the detection of *spontaneous* coronary spasm during diagnostic cardiac catheterization in our institution. In all patients aged ≤60 years with a history of angina pectoris of ≤1 year in duration, antiplatelet agents were discontinued at least 1 week, and long-acting nitrates at least 12 hours before the study. No patient was receiving calcium-channel blocking agents at the time of the study. Premedication consisted of oral phenobarbital sodium and diphenhydramine hydrochloride, 50 mg each, in 36 patients, or oral diazepam, 10 mg, in 10 patients. Coronary angiography was carried out both before and after the intracoronary injection of 100 to 200 μg of nitroglycerin. All patients in this group who were found to have single-vessel disease without spontaneous spasm, met the proper criteria (proximal, critical, noncalcified stenosis), and gave informed consent (39 patients) underwent PTCA at a later date. Patients with single, fixed lesions and superimposed spasm (7 patients) were treated medically (3 patients) unless the fixed component was critical (≥60% reduction of normal luminal diameter). Twenty-eight patients were referred for PTCA after coronary angiography done elsewhere. Some were aged >60 years or gave a history of angina pectoris for longer than 1 year. Precise information on the type and time of discontinuation of antiplatelet and coronary vasodilating drugs before the initial diagnostic angiography is not available in these patients. Premedication varied according to referring center, consisting of diazepam, diphenhydramine, or phenobarbital sodium alone or in combination. Nitroglycerin was administered orally before coronary angiography in 5. One patient (Patient 10 of the present series) had spontaneous variation of coronary diameter during diagnostic angiography. In these 28 patients, angiography was repeated before and after intracoronary nitroglycerin on the day of PTCA, before PTCA was attempted. In 2 (Patients 2 and 8 of this series), spasm was first demonstrated at that time. Thus, spontaneous coronary spasm was detected before PTCA in 10 patients. In 1 of the 39 patients initially studied by us, spasm was disco ered for the first time on angiography repeated shortly aft PTCA because of recurrent symptoms. The cardiac medic tion before PTCA in all 74 patients consisted only of lon acting nitrates which were discontinued at least 12 hours b fore PTCA except in Patient 9. During PTCA, 200 μg bolus of intracoronary nitroglycerin were given before, during, an after dilating catheter manipulation in all patients.

All angiograms from our institution and elsewhere wer carefully reviewed for visual evidence of diameter changes a the site of stenosis. In 15 patients, a significant variation wa deemed to be present on inspection. This was confirmed b measurement in 11 patients; in 4 the subjective impression wa not borne out by quantitative analysis. The objective diagnos of coronary spasm was made when the measured average degree of stenosis on the angiogram decreased by ≥20% of th adjacent normal lumen diameter or when a totally occlude vessel reopened to any extent (Patient 9) either spontaneousl or after intracoronary nitroglycerin, or when a stenosed vess developed transient total occlusion (Patient 6). Each angio gram was analyzed independently by 2 of us (LGB and LRL Measurements were made on the frames with the most an least severe stenosis in 2 projections* and averaged. Thus, fo each of the 2 states—spasm and no spasm—the results rep resent the mean of 8 measurements. Measurements were mad directly on the screen of a model XR-35 Vanguard projecto using a magnifying glass with metric grid. The 20% minima significant difference was chosen for consistency with th value adopted by the National Heart, Lung, and Blood In stitute Executive Committee on PTCA to define success whe using this technique. However, the maximal difference be tween the means of 4 measurements made 3 months apart i each of 10 control angiograms was <10% for both co-au thors.

The following clinical definitions have been employed t classify patients in this series: *Stable angina pectoris:* pre dictable, exertional chest pain with no or slow progressio after its inception, without episodes at rest or during sleep *Unstable angina pectoris:* (1) chest pain of recent origin (≤ months) with episodes at rest or during sleep, regardless of th type of initial clinical presentation; (2) chest pain of > months' duration but with recent episodes at rest or durin sleep. *Variant angina pectoris:* chest pain of variable duratio at rest with transient S-T segment elevation in the leads facin the myocardial zone subserved by the stenosed coronary ar tery, responding quickly to nitroglycerin. *Intermediate syn drome:* 1 or more episodes of prolonged chest pain (≥2(minutes) usually with transient ST-T changes, no new Q waves or enzymes elevations, and incomplete response to ni troglycerin. *Subendocardial myocardial infarction:* prolonge episodes of chest pain (≥30 minutes) associated with evolving sustained ST-T changes but no new Q waves, and significan cardiac enzyme elevations. The significance of differences fo variables between patients with and without coronary artery spasm was assessed using the chi-square test and the unpaired Student's *t* test.

TABLE I Clinical Data in 11 Patients With and 63 Patients Without Demonstrated Coronary Spasm

	Spasm Group	No Spasm Group	p Value
Patients (n)	11	63	
Age (yr)	31–63 (48)	31–69 (53)	<0.01
Sex (male/female)	7/4	51/12	NS
Duration of symptoms (mo)	0–36 (7)	0–144 (10) 0–48 (7)*	NS
Type of symptoms			
Stable AP	0/11	9/63	NS
Unstable AP	3	35	...
Variant AP	2	1	...
Intermediate syndrome	4	3	...
Subendocardial MI	2	5	...
Transmural MI	0	10	...
ADA/RCA†	9/2	42/18	NS
Success/total number of PTCA	6/8	39/63	NS
Complications/total number of PTCA	1/8	8/63	NS

* Patient with 144 months' duration of symptoms left out.

† Ratio of anterior descending to right coronary artery stenosis. Three patients in the no spasm group with circumflex artery stenosis are left out.

AP = angina pectoris; MI = myocardial infarction; NS = not significant. For definitions, see the Methods section.

Results

Eighty-two patients were admitted to the Medica College of Pennsylvania for the performance of PTCA as of March 31, 1982. Eight had stenosis of 1 or more saphenous vein grafts and were excluded from this se ries. The remaining 74, 58 men and 16 women aged 31

* Usually 30° right anterior oblique and 45° to 50° left anterio oblique projection with 30° craniocaudal rotation for the left coronary artery, and 30° right anterior oblique and 35° to 40° left anterior oblique projection for the right coronary artery.

to 69 years (mean 51), all with single-vessel disease, are the subjects of this report. Fourteen (19%) had evidence of coronary spasm associated with fixed stenosis. In 3 patients, spasm developed only during PTCA presumably from irritation caused by the dilating catheter; they are included in the subgroup without spontaneous coronary spasm. Eleven patients constitute the coronary spasm subgroup proper. Their age, sex, duration of symptoms, type of angina pectoris, and coronary artery involved are given in Table I. PTCA was carried out in 8 by the technique of Grüntzig et al,[4] while 3 in whom the fixed component of the mixed stenosis was noncritical were treated medically. In 63 patients, spontaneous coronary spasm was not apparent; all underwent PTCA. Table I shows that the composition of the subset with spontaneous coronary spasm did not differ from the subset without spasm except for age.

Coronary spasm superimposed on subcritical fixed stenosis (Patients 1 to 3): There were 3 patients in this group, with mixed (fixed plus spastic component) stenosis of 80, 66, and 70%, respectively of the left anterior descending artery which decreased to 45, 30, and 23% of the luminal diameter after intracoronary nitroglycerin. No chest pain developed during diagnostic angiography in any of these patients. All were treated medically with nitrates and nifedipine. Patients 1 and 2 have been followed up for 35 and 10 months, respectively, with no recurrence of chest pain in the former and rare and mild episodes in the latter. In Patient 3, the attacks of angina pectoris worsened despite medication and he had an inferior myocardial infarction 6 months later. Repeat coronary angiography disclosed de novo occlusion of the previously unobstructed right coronary artery and progression of the fixed component of the left anterior descending stenosis from 23 to 62%. Coronary artery bypass surgery to the left anterior descending and right coronary arteries was carried out. Thirteen months later, the patient has occasional mild episodes of chest pain at rest despite administration of nitrates and nifedipine.

Critical (>60%) fixed stenosis: Superimposed spasm before PTCA or on follow-up (Patients 4 to 11): There are 8 patients in this group; in 7 (Patients 4 to 10) spasm was documented before PTCA and in Patient 11 it was documented on follow-up. In Patients 4 and 5, mixed stenoses of 90 and 82% (Fig. 1, top left)

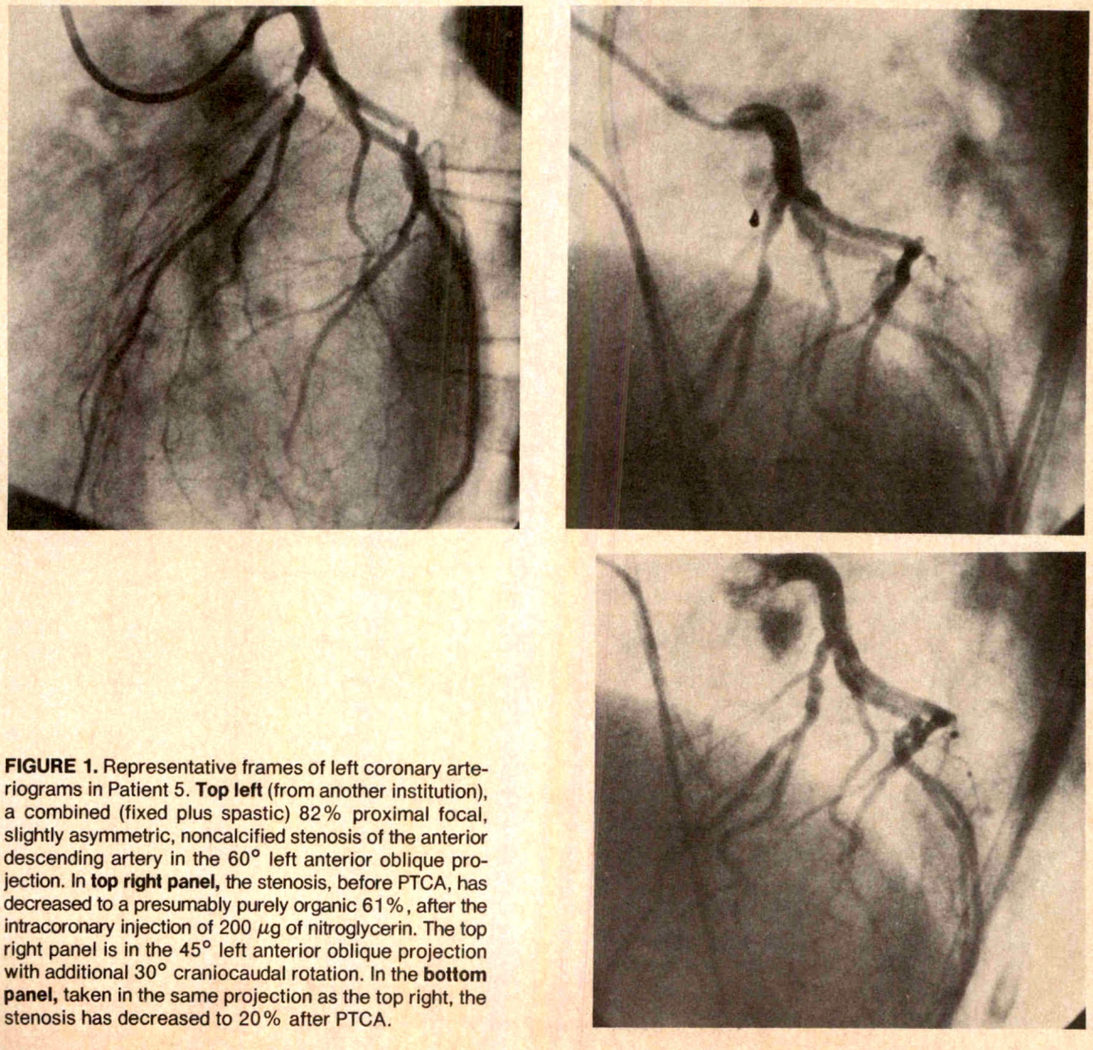

FIGURE 1. Representative frames of left coronary arteriograms in Patient 5. **Top left** (from another institution), a combined (fixed plus spastic) 82% proximal focal, slightly asymmetric, noncalcified stenosis of the anterior descending artery in the 60° left anterior oblique projection. In **top right panel,** the stenosis, before PTCA, has decreased to a presumably purely organic 61%, after the intracoronary injection of 200 μg of nitroglycerin. The top right panel is in the 45° left anterior oblique projection with additional 30° craniocaudal rotation. In the **bottom panel,** taken in the same projection as the top right, the stenosis has decreased to 20% after PTCA.

of the left anterior descending artery decreased to 66 and 61%, respectively (Fig. 1, top right) after intracoronary nitroglycerin, and were further reduced to 40 and 20% (Fig. 1, bottom) after PTCA. In Patient 6, a 90% fixed stenosis of the right coronary artery became totally occluded during diagnostic angiography, and had prompt response to intracoronary nitroglycerin; it decreased to 32% after PTCA. In Patient 7, a mixed, 68% left anterior descending stenosis decreased to 26% after intracoronary nitroglycerin but was found to have become fixed at 78% on repeat catheterization performed because of recurrent symptoms despite nitrates and nifedipine. Percutaneous transluminal coronary angioplasty reduced the fixed stenosis to 17%. Patient 8 had crushing chest pain with marked S-T segment elevation in V_1–V_3 on the day of PTCA while on the catheterization table but before catheter insertion. Sublingual nitroglycerin quickly terminated the attack. Percutaneous transluminal coronary angioplasty reduced the fixed left anterior descending stenosis from 61 to 19%. Patient 9, with intermediate syndrome, was found on diagnostic angiography to have 100% occlusion of the right coronary artery which decreased to 90% after intracoronary nitroglycerin and further to 80% after the intracoronary administration of 300,000 units of streptokinase. One week later, during attempted PTCA, the stenosis was 60%. The procedure was complicated by intimal dissection, with chest pain and S-T segment changes. Emergency coronary artery bypass surgery was successful but a transmural inferior myocardial infarction developed. Patient 10 had spontaneous variation of a mixed left anterior descending stenosis between 68 and 92% on diagnostic angiography done elsewhere. During unsuccessful PTCA, he had 100% occlusion of the left anterior descending artery with moderate chest pain. Intracoronary nitroglycerin restored flow, and he later underwent elective uneventful coronary artery bypass surgery. Patient 11, with atypical angina pectoris and a previous subendocardial myocardial infarction, had successful reduction by PTCA of a seemingly purely organic 70% left anterior descending stenosis to 30%. Shortly thereafter, atypical angina pectoris resumed despite oral nitrates. Repeat angiography revealed a 70% stenosis at the site of PTCA which decreased to 40% after intracoronary nitroglycerin. In addition to Patients 8 and 10, chest pain was present during part of angiography in Patients 6 and 9 but subsided after intracoronary nitroglycerin; Patients 4, 5, 7, and 11 remained asymptomatic.

The follow-up in this group ranges from 6 to 31 months (mean 17). Except for Patients 9 and 10, all others have been receiving nitrates and nifedipine. There has been complete suppression of angina pectoris in Patients 6 to 8. In Patients 4, 5, and 11, rare and mild episodes of chest pain occur despite medication. In Patient 5, repeat angiography showed no progression of the residual stenosis at the site of PTCA. However, diffuse spasm of the right coronary artery was discovered which reduced the lumen by 61% and was promptly relieved by intracoronary nitroglycerin. Patients 9 and 10, 9 and 12 months postoperatively, have no symptoms and are taking no cardiac medication.

Discussion

Coronary artery spasm can be recognized angiographically by transient variation in segmental luminal diameter. For detection, frames with and without spasm must be compared. Grading by visual inspection has been shown to be hazardous due to large intra- and interobserver error.[5–8] However, quantitative grading of the subjectively chosen vessel borders has proven precise and reproducible[9–11]: for vessels of ≥3 mm diameter—the size of proximal coronary arteries in humans—the mean observer error is about 5%[9,10] with a maximal error of 11% in 1 series.[11] To be acceptable, the minimal diagnostic change in vessel diameter must exceed the maximal measuring error. The minimal 20% difference in luminal diameter chosen as diagnostic of spasm in the present series far exceeds the maximal error made by each of 2 co-authors in 10 control angiograms. A second type of error could be incurred, independent of inaccuracies in measurements. Nitroglycerin has a vasodilating effect in organically stenosed as well as normal coronary artery segments in vivo.[12] Ignorance of this effect could lead to incorrect labeling of the physiologic relaxation of vascular tone at the site of stenosis after intracoronary nitroglycerin as relief of spasm. In a recent report,[12] the cross-sectional area at the site of severe organic stenoses comparable to what was found in most patients in this series increased by as much as 36% after sublingual nitroglycerin administration, corresponding to a diameter increase of 16.5%. However, when the ratio between obstructed and normal coronary segments was employed, as done by us, the percent stenosis was the same both before and after nitroglycerin because diseased and normal segments dilate proportionately.[12] From the foregoing considerations we are confident that the diagnosis of coronary spasm was correct in all patients of this series. Figure 1 provides the visual verification of the smallest percent change in luminal diameter (21%) in our patients.

Coronary spasm is transient and unpredictable and may affect the outcome of PTCA, hence the need for its recognition. When present at the beginning of angiography, spasm can be unmasked by repeated visualization after coronary vasodilators; when initially absent, it can be detected by spontaneous or induced development during the study. Sublingual nitroglycerin may fail to relieve preexistent coronary spasm. Thus, for maximal sensitivity, we advocate the intracoronary route.[13] Although we are not aware of failures to unmask it using this approach, the possibility cannot be excluded. The spontaneous development of spasm is easily detected by reduction in lumen diameter during the sequential coronary injections. When absent during coronary angiography, coronary spasm can be induced by provocative testing.[14,15] However, because of the attendant risks,[16,17] we are reluctant to use provocative testing in patients with high-grade fixed stenosis.

The 15% incidence of unprovoked coronary spasm in this series is higher than we expected. Even so, this percentage probably represents only its random occurrence in our population at a given time, as opposed to true prevalence which may be higher. The mixed

obstruction spasm produces in these patients is often subtotal and asymptomatic.

Is there a possible explanation for the relatively large number of patients with coronary spasm among our candidates for PTCA? Evidence is mounting that coronary spasm plays a significant role in the pathogenesis of chest pain in all the unstable angina pectoris syndromes by causing a transient reduction or interruption of coronary blood flow while myocardial oxygen demand remains stable.[3,18,19] The majority of patients in this series, 65 of 74, had some form of unstable angina pectoris or had acute myocardial infarction after an unstable course; the discovery of spontaneous coronary spasm in 11 is not surprising. It is possible that, had provocative tests been carried out, more cases of spasm might have been discovered. Thus, the high incidence of coronary spasm probably just reflects the high prevalence of unstable angina pectoris in our series. This, in turn, may result in part from the selection criterion for PTCA recommending a duration of angina pectoris of ≤1 year.[4] This criterion favors clustering of patients with angina pectoris of recent onset, 1 form of unstable angina pectoris, among candidates for this procedure. On this basis, we would expect a relatively high prevalence of coronary spasm in other PTCA laboratories as well.

The demonstration of coronary spasm superimposed on a fixed stenosis has been thought to represent a relative contraindication to the performance of PTCA.[20] This has been based on several lines of reasoning. Historically, the supposedly adverse influence of a spastic "diathesis" on the results of coronary artery bypass surgery in patients with Prinzmetal's angina and mixed stenoses has been stressed,[21] although not without subsequent challenge.[22,23] More pertinently, 1 late death in the original report by Grüntzig et al[4] and 2 early deaths in the National Heart, Lung, and Blood Institute registry[24] may have been caused by spasm. The present series reveals a 75% (6 of 8) success rate in patients with spasm and a 62% (39 of 63) success rate in patients without it, suggesting that spasm does not reduce the chance of early success. The rate of complications requiring emergency coronary artery bypass surgery is similar in patients with spasm (1 of 8, or 13%) and without spasm (8 of 63, or 13%).

Because of its propensity to recur, coronary spasm has obvious relevance to the long-term follow-up of patients in this series. The follow-up of the 3 patients treated medically with nitrates and nifedipine because of a subcritical organic component of a mixed stenosis indicates that, although usually effective, coronary vasodilators cannot totally prevent the recurrence of angina pectoris and the development of complications in this subset of patients. The 6 patients treated successfully by PTCA have all received nitrates and nifedipine. Three of the 6 are asymptomatic while in the other 3 rare, mild episodes of atypical chest discomfort persist, qualitatively similar to the attacks before PTCA. In 2 of the latter 3 patients, the persistence of coronary spasm has been documented, in 1 of them in a different artery than the 1 successfully dilated. Thus, while the critical fixed component of a mixed stenosis may be relieved, spasm may recur and warrants long-term use of nitrates and calcium blockers. The 2 patients who underwent coronary artery bypass surgery after unsuccessful PTCA remain asymptomatic without vasodilator medication. Spasm therefore has not adversely affected the long-term results of coronary artery bypass surgery in these 2 patients.

Assessment of Plexectomy in the Treatment of Severe Coronary Spasm in Patients With Normal Coronary Arteries

SIMON WEBER, MD, GEORGES-PATRICK DONZEAU-GOUGE, MD, SYLVAIN CHAUVAUD, MD, GUY PICARD, MD, FRANÇOIS GUERIN, MD, ALAIN CARPENTIER, MD, and MICHEL DEGEORGES, MD

Surgical denervation of the heart by plexectomy was performed in 3 patients with variant angina, documented coronary spasm, and normal findings on coronary angiography. In all cases, spasm had already been responsible, preoperatively, for myocardial infarction and recurred thereafter in another territory despite medical therapy with a combination of nitrates and calcium antagonists. Plexectomy was performed using a standardized technique. The effectiveness of surgical suppression of cardiac autonomic innervation was confirmed postoperatively by pharmacologic tests. In 2 patients inferior myocardial infarction developed in the early postoperative period; in the third patient, coronary spasm recurred 3 weeks after plexectomy. Thus plexectomy, despite an adequate suppression of autonomic innervation, was ineffective in all cases and may even have been harmful in 2 patients. These data contradict the good results obtained by plexectomy associated with aortocoronary bypass in patients with variant angina and fixed stenotic coronary arteries. This discrepancy may be accounted for by a different pathophysiologic mechanism of vasospasm in normal coronary arteries and in diseased arteries at the site of the atheromatous stenosis. Thus, plexectomy should not be considered in the treatment of vasospasm involving normal coronary arteries, even if medical therapy fails to achieve satisfactory control of variant anginal attacks.

The introduction of calcium antagonists has provided a satisfactory means of preventing variant angina attacks in most patients with coronary spasm and normal coronary arteries.[1–3] However, in a limited number of patients, recurrence of coronary spasm cannot be controlled medically and may lead to myocardial infarction (MI) or sudden death.[3–5] In some patients with Prinzmetal's variant angina, the role of the autonomic nervous system in the pathophysiology of coronary spasm has been well established[6,7]; surgical suppression of the cardiac autonomic nervous system has therefore been advocated by several investigators in the treatment of this syndrome.[8–13] Experience with this procedure is limited, however, and the available results are contradictory. Some workers report good results when denervation is associated with coronary artery bypass grafting (CABG) in patients with coronary spasm and significant organic stenosis[10]; others have had poor results, high operative mortality rates, and recurrence of spasm when denervation was performed alone or in association with CABG.[12] These conflicting findings could be explained by differences in patient selection and operative procedure. In this report, we describe the results of cardiac denervation by plexectomy in 3 patients with severe variant angina refractory to maximal medical therapy. All 3 patients had normal coronary angiograms, and spasm was therefore the sole cause of myocardial ischemia. Postoperatively, the 3 patients

underwent pharmacologic testing to prove full suppression of the autonomic cardiac innervation and to therefore confirm a uniform surgical outcome.

Patients Studied

Plexectomy was considered only when maximal medical therapy failed to control attacks of variant angina. In all 3 patients, despite medical treatment, coronary spasm had already provoked MI and occurred thereafter in another vascular territory. We used the operative procedure described by Bertrand et al.[10] A continuous intravenous infusion of nitroglycerin was begun before surgery. All patients were receiving nifedipine, and the drug was continued during the perioperative period. A bolus of lidocaine was infiltrated under the aortic root to avoid a possible spasm induced by the manipulation of Wrisberg's ganglia. Then, using the 3-step procedure described by Bertrand et al, as much as possible of the major cardiac plexus, including the nerves to the right coronary artery, was resected.

Case 1: A 34-year-old man had severe chest pain at rest accompanied by a 3 mm S-T segment elevation in leads D_2, D_3, and Vf. Sublingual nitroglycerin relieved pain and the electrocardiogram returned to normal. Nifedipine (20 mg) and isosorbide dinitrate (20 mg) were administered orally, but 1 hour later chest pain recurred, accompanied by S-T segment elevation in leads V_1 to V_4. Despite intravenous nitroglycerin, an anterior myocardial infarction (MI) developed. Coronary angiography was performed 1 week later while the patient was receiving nifedipine and isosorbide dinitrate. Left ventriculography showed signs of anterior hypokinesia and a depressed ejection fraction (35%). The left coronary angiogram was normal. During right coronary catheterization, chest pain occurred with S-T segment elevation in leads D_2, D_3, and Vf; on right coronary angiography an 80% narrowing of the midportion of the right coronary artery was observed, and was reversed by intravenous nitroglycerin. Four hours after plexectomy while 35 μg/min of nitroglycerin was being infused, S-T segment elevation in inferior leads D_2, D_3, and Vf occurred and was soon followed by second-degree atrioventricular block. Despite increasing the nitroglycerin infusion rate to 60 μg/min and administration of sublingual nifedipine, spasm could not be reversed and the patient had an inferior MI. Necrosis was complicated by severe acute left ventricular failure. During the following days no chest pain was noted and Holter monitoring showed no asymptomatic S-T segment modification. The patient had chronic left ventricular failure and is presently in New York Heart Association class III.

TABLE I Results of Pharmacologic Testing

	Case 1		Case 2		Case 3	
	HR (beats/min)	SBP (mm Hg)	HR (beats/min)	SBP (mm Hg)	HR (beats/min)	SBP (mm Hg)
Phenylephrine (μg/min)						
0 (baseline)	96	145	89	126	93	139
50	97	150	87	132	92	141
100	93	178	88	155	90	164
200	94	195	85	182	91	186
Atropine						
Baseline	94	140	88	131	91	141
Maximal value during 30 min	99	148	94	134	95	145

HR = heart rate; SBP = systolic blood pressure.

Case 2: A 51-year-old man had episodes of nocturnal chest pain during 1 week; after 1 episode which lasted over an hour, electrical signs of anteroseptal MI were recorded. The patient was admitted to the coronary care unit, where attacks of Prinzmetal's variant angina recurred despite administration of nifedipine (80 mg/day) and intravenous nitroglycerin, with transient S-T segment elevation involving either the anterior leads V_1 to V_4 already involved in the MI or the inferior leads. Both left and right coronary arteries were normal at angiography. Left ventriculography showed limited anteroapical akinesia; the ejection fraction was moderately reduced (45%). Twelve hours postoperatively, S-T segment elevation occurred in inferior leads D_2, D_3, and Vf and could not be reversed by increasing the nitroglycerin infusion rate from 20 to 50 μg/min or by administrating sublingual nifedipine. Inferior MI developed. Recovery was uneventful. Subsequently, the patient received nifedipine, 80 mg/day, and 80 mg/day of isosorbide dinitrate; no recurrence of variant angina was noted and Holter monitoring showed no asymptomatic S-T segment change.

Case 3: A 47-year-old woman was admitted to the coronary care unit 3 hours after the onset of chest pain. Electrocardiography showed inferior MI; her recovery was uneventful. Coronary arteriography was performed 3 weeks later while the patient was receiving nifedipine, 60 mg/day, and 60 mg/day of isosorbide dinitrate. Left ventriculography showed inferior akinesia, and the ejection fraction was 52%. After ventriculography, chest pain developed and S-T segment elevation was recorded in precordial leads. The left coronary angiograms showed stenosis of the proximal part of the left anterior descending artery. This stenosis was completely reversed by the intravenous administration of nitroglycerin. The right coronary artery was normal. Plexectomy was performed thereafter and the postoperative period was uneventful; the patient was discharged on the 11th postoperative day with nifedipine, 60 mg/day. Two weeks later the patient had chest pain, and electrocardiographic monitoring recorded transient S-T segment elevation in the inferior leads, already involved in the previous MI. High-dose isosorbide dinitrate and nifedipine controlled the symptoms of variant angina. The patient remained symptom-free thereafter, and repeated Holter monitorings showed no S-T modifications.

Control of the Suppression of Autonomic Command of the Heart

Autonomic nerve fibers were found in all resected tissues submitted for histologic examination; however, these findings indicate only that some of the cardiac nerves were resected and cannot establish that all physiologically significant innervation was suppressed.

Since no perioperative criteria can establish that all physiologically significant cardiac nerves had been resected, all 3 patients underwent pharmacologic assessment of autonomic control of the heart. This procedure was performed within 2 to 3 weeks after surgery. In order to evaluate the bradycardic baroreceptor reflex response to an increase in arterial pressure, a phenylephrine infusion was administered. Phenylephrine, a vasoconstrictive alpha-adrenergic receptor agonist, was infused at increasing rates from 50 to 200 μg/min to increase blood pressure. Infusion rates were doubled every 5 minutes. The electrocardiogram was monitored during the infusion to determine heart rate. Denerva-

tion was considered satisfactory if no significant reflex bradycardia (>5% of baseline value) was noted. Atropine was also used to assess the effectiveness of parasympathetic suppression. After the phenylephrine infusion and the return of arterial pressure to baseline values, an intravenous bolus of 0.02 mg/kg of atropine was administered. The electrocardiogram was monitored over the following 30 minutes. Denervation was considered effective if no significant increase (<5% of the baseline value) in heart rate occurred.

The results of the pharmacologic testing are summarized in Table I. The increase in arterial pressure elicited by phenylephrine provoked no significant reflex bradycardia, and atropine induced no significant increase in heart rate. These findings indicate suppression of the autonomic control of the heart.

Discussion

In our 3 patients, despite the satisfactory surgical suppression of autonomic innervation of the heart, plexectomy failed to prevent recurrent coronary spasm. Moreover, in 2 cases MI occurred in the immediate postoperative period and was probably secondary, in these patients with variant angina and angiographically normal coronary arteries, to occlusive coronary spasm. The cause-and-effect relation between surgical denervation and MI is difficult to establish with certainty in these patients with severe recurrent spasm that had already been responsible for previous MI. Nevertheless, MI in the immediate postoperative period cannot be considered a simple coincidence, and plexectomy may have had deleterious effects in the 2 patients concerned. Our study group includes highly selected patients. In all subjects, spasm was the sole cause of ischemia; coronary arteries were entirely normal at angiography without any significant stenosis. Spasm was extremely severe and had already been in each patient, before surgery was performed, the cause of MI. In all cases, spasm was documented despite medical management with a combination of nitrate and the calcium antagonist nifedipine. Thus, our study group represented patients with the most severe form of vasospasm and cannot therefore be considered representative of the entire population of patients with Prinzmetal's variant angina.

The negative results we present agree with those obtained by Clark et al[12] in 8 patients in whom cardiac denervation was achieved by plexectomy or autotransplantation. Buda et al[13] reported a case of coronary spasm occurring in a patient 2 years after he had received a heart transplant. The absence of reinnervation of the transplanted heart was demonstrated by pharmacologic testing and the spasm involved, as in our 3 patients, the right coronary artery. Bertrand et al[14,15] reported the case of a patient treated by autotransplantation for Prinzmetal's variant angina involving normal coronary arteries. Eighteen months after surgery, chest pain recurred and the electrocardiogram showed signs of variant angina. In contrast to these negative results involving patients with pure spasm, Bertrand et al[10] reported excellent results when plexectomy was associated with CABG in patients with spasm superimposed on significant fixed stenosis. Thus, plexectomy seems to have clearly different results when performed alone in patients with spasm and without coronary narrowing or in association with CABG in patients with significant stenosis. These drastically different results after suppression of cardiac autonomic innervation raise a question about the heterogeneity of the pathophysiology of coronary spasm. The currently proposed mechanisms of coronary spasm include abnormalities of the autonomic control of the heart, local production of vasoconstrictive metabolites, increased levels of circulating vasoactive substances, or increased responsiveness of the coronary arteries to these substances. In a given patient, spasm may be provoked by any one or more of these various mechanisms; moreover, the sequence of pathophysiologic events leading to spasm may vary from one patient to another. It is conceivable that the autonomic nervous system plays the predominant role in producing spasm superimposed on significant coronary stenosis but that vasospasm of normal coronary arteries may be, at least in some patients, independent of any abnormality of the neural control of the heart. Such a difference in pathophysiology would explain the discordant results obtained after plexectomy performed alone on normal coronary arteries or in association with CABG on stenotic arteries. In 2 of our patients, plexectomy may have been responsible for worsening of coronary spasm; a possible explanation for this phenomenon may be the occurrence of a denervation hypersensitivity increasing the vasoconstrictive response of the coronary artery to circulating catecholamines. It should be noted that in all 3 cases, postoperative coronary spasm involved the right coronary artery.

Suppression of the vasodilator parasympathetic tone of the right coronary artery may provide the explanation for the observed events. It is well established that the parasympathetic neuromediator acetylcholine causes the release of norepinephrine by the postganglionic sympathetic nerve fiber.[16,17] Norepinephrine, through its action on the coronary artery alpha-adrenergic receptors, induces vasoconstriction. Thus, by indirect effect, the parasympathetic tone is involved in coronary vasoconstriction. However, the direct effect of parasympathetic stimulation is coronary vasodilation mediated by muscarinic acetylcholine released by the postganglionic parasympathetic nerve ending.[18] The right coronary circulation may be physiologically more sensitive to the direct cholinergic vasodilatation and therefore may become more susceptible to the action of local or circulating vasoconstrictive metabolites once plexectomy is performed.

Effects of Early Postmyocardial Infarction Exercise Testing On Self-Perception and Subsequent Physical Activity

CRAIG K. EWART, PhD, C. BARR TAYLOR, MD, LINDA B. REESE, MA, and ROBERT F. DeBUSK, MD

The effects of exercise testing 3 weeks after clinically uncomplicated myocardial infarction (MI) on subsequent physical activity were evaluated in 40 consecutive men with a mean age of 52 ± 9 years. Patients' confidence in their ability to perform various physical activities was evaluated with self-efficacy scales which patients completed before and after a symptom-limited treadmill exercise test. Increases in confidence (self-efficacy) for activities similar to treadmill exercise (walking, stair climbing, and running) were greatest after treadmill exercise, whereas increases for dissimilar activities (sexual intercourse and lifting) were greatest after test results were explained by a physician and nurse. The intensity and duration of subsequent physical activity at home were more highly correlated with self-efficacy after treadmill exercise than with peak treadmill heart rate. Of the 8 patients whose treadmill tests were limited by angina pectoris, 7 had self-efficacy scores which remained low after treadmill testing or which decreased from initially high values after treadmill testing. These patients had lower peak heart rates and work loads than patients whose self-efficacy increased or remained high after treadmill testing. After MI, patients' perception of their capacity for physical activity and their actual patterns of subsequent physical activity are influenced by early treadmill testing in a manner which is congruent with these patients' treadmill performance.

Patients often fear physical activity after clinically uncomplicated myocardial infarction (MI) and may limit or postpone their usual activities, including occupational work, until long after it is medically safe to resume them. Standard psychological tests, such as the Minnesota Multiphasic Personality Inventory, do not permit the identification of patients whose concerns about physical activity levels may be medically unwarranted: these test methods yield global assessment of psychological status or symptoms which are poorly correlated with discrete behaviors such as return to work.[1]

Scales have been developed to study the relation between self-perceived efficacy (confidence) and behavior. While an individual's self-efficacy judgments may vary from 1 activity to another, the level of self-efficacy reliably predicts whether a particular activity will be attempted.[2] We considered that self-efficacy scales might reliably measure the increased confidence in the ability to resume usual postinfarction activities that is observed in patients performing treadmill exercise soon after clinically uncomplicated MI.

The present study had 3 major goals: (1) to determine the correspondence between pretreadmill self-efficacy and treadmill performance, (2) to measure changes in self-efficacy resulting from treadmill testing and subsequent counselling by a physician and nurse, and (3) to determine whether subsequent physical activity in the normal environment was more closely related to exercise performance or to self-efficacy after exercise testing.

Methods

Patients who were free of unstable angina pectoris and clinical heart failure, including an S_3 gallop 3 weeks after MI, were eligible to undergo treadmill exercise testing. Forty consecutive men (mean age 52 ± 9 years) participated in this project; 90% of the patients were married and most were of middle or upper middle socioeconomic status.

The overall design of the study is depicted in Table I. Before treadmill testing, patients were asked to complete a set of

TABLE I Measurement of Self-Efficacy and Physical Activity

Days After MI	Sequence of Events*
18–20	3-day activity record
21	SE_1/TM/SE_2/counselling/SE_3
25–28	3-day activity record

* For the 18 patients who completed activity logs and for all patients during the day of the treadmill test (TM). SE = self-efficacy scale.

questionnaires including a demographic information form, measures of depression (Beck et al,[3] Hamilton[4]) anxiety (Spielberger et al[5]), and marital adjustment (Locke-Wallace[6]) and self-efficacy. A set of 6 self-efficacy scales was developed to measure patients' self-perceived ability to carry out the following activities: (1) walking, (2) running distances ranging from 1 block to 5 miles, (3) climbing stairs for distances from a few steps to 4 flights, (4) engaging in sexual intercourse (not including foreplay) from 1 to 20 or more minutes, and (5) lifting objects weighing 10 to 75 pounds (4.5 to 34 kg). A sixth item requested an overall estimate of ability to tolerate physical exertion on a 6-point scale ranging from "very light" to "extremely hard." Patients were asked to indicate whether or not they thought they could perform a given level of activity and to record their level of confidence in this judgment. Confidence estimates were made on a scale which ranged from 10 (quite uncertain) to 100 (completely certain). A similar methodology was used by Bandura[7] and others in previous studies of self-efficacy. Self-efficacy estimates do not change with repeated testing in the absence of interventions.[7,8]

A patient's self-efficacy score for a given task (such as running) was the sum of the confidence estimates the patient gave for successive levels of the task (for example, run 1 block, run 2 blocks, run 5 blocks) divided by the number of levels on that particular scale (for example, 9 levels for running). Scores were computed for each of the 5 physical tasks and for general exertion ratings. A seventh self-efficacy score, created by summing the scores for running, walking, and climbing, was used to measure the correspondence between postexercise test efficacy estimates and activities in the normal environment.

A subgroup of 18 patients reported their levels of physical activity for 3 days before the exercise test using activity logs that they were given at the time of hospital discharge. On the activity logs, each day was divided into 3 "self-observation" periods: morning, afternoon, and evening. Patients were asked at the end of each of the 3 periods to indicate the most strenuous physical activity they had performed during that period, the duration of this activity, and the peak heart rate attained during the activity. Patients were taught to measure their pulse rate before hospital discharge.

Preliminary studies had indicated that patients were relatively less active on the day after exercise testing than during the following 3 days. Accordingly, activity levels on the 3 days immediately before exercise testing were compared with levels recorded on the same 3 days of the following week.

All patients performed symptom-limited treadmill exercise testing using a modified Balke protocol[9] to endpoints of limiting symptoms or to decrease in systolic pressure of 10 mm Hg or more compared with an earlier stage of exercise. Immediately after the test, patients completed the self-efficacy questionnaire a second time and were interviewed, first by a cardiologist and then by a specially trained nurse. The cardiologist explained the results of the test to the patient in detail and discussed with the patient his capacity to perform various physical activities such as walking, jogging, and stationary cycling. The nurse then reinforced the cardiologist's "clearance" to perform these activities, instructing patients to avoid heart rates exceeding 85% of the highest heart rate at which angina pectoris or ischemic S-T segment depression were absent during exercise testing. After the nurse's interview, patients completed the self-efficacy questionnaires a third time and were given new activity logs.

The accuracy of self-reported activity and heart rate levels was determined by direct physiologic measurement of physical activity and heart rates using a portable solid-state computer (Vitalog).[10] The Vitalog system consists of a CMOS solid-state microcomputer (MC-2) interfaced with a read-only memory and a random-access memory, a motion sensor, and an analog R-wave detector connected to the chest by electrocardiographic electrodes. The microcomputer contains 36 K bits of CMOS random-access memory. The MC-2 measures 4 × 8 × 12 cm, weighs 0.1 kg, and is worn on the belt. The motion sensor, which is attached to the right lateral thigh by tape, consists of 6 liquid mercury tilt switches aligned on the faces of a cube. Movement in any direction causes the switches to open and close. The number of openings and closings each minute is accumulated and stored logarithmically. In a previous study, we found good correspondence between heart rate recorded by the MC-2 and by an ambulatory electrocardiogram and between physical activity levels recorded by the MC-2 and those observed during gradually increasing treadmill work loads.[10] For purposes of the present study, the total number of heart beats recorded per minute was stored.

The monitor was worn during the 3 days on which patients recorded their activity levels before and after exercise testing. The Vitalog was randomly allocated to 10 of the 18 patients who completed activity logs. Clinical characteristics, age, treadmill performance, and self-efficacy of the 18 patients who completed activity logs were similar to those of the 22 patients who did not complete activity logs.

Vitalog records were compared with self-report for each of the 3 daily periods on each of the 3 days. Agreement between self-reported physical activity and that recorded on the MC-2 was determined for moderate and greater levels of physical activity. "Moderate" physical activity on the MC-2 was classified as a combination of heart rate and physical activity intensity which exceeded that observed during the patient's treadmill workload of 4 mets. The duration and intensity of physical activity reported as "moderate" or greater corresponded to that recorded on the MC-2 in 94% of comparisons.

Results

Patients' clinical status, treadmill test performance, and psychologic test scores showed them to be a relatively uncomplicated and comparatively well-adjusted group. Mean scores for depression, anxiety, and marital adjustment did not differ from norms derived from healthy adults.[11] Patients attained an average treadmill work load of 6.1 ± 1.4 mets and an average peak heart rate of 132 ± 15 beats/min. More than two thirds of the tests were stopped because of fatigue and shortness of breath, 20% were stopped because of exertional angina pectoris, and 15% because of a decrease in systolic pressure. No test was discontinued because of cardiac signs (blank faces, staggering gait) or advanced grades of ventricular ectopic activity.

Ten patients had a history of angina pectoris for at least 3 months before MI. Seven patients had angina pectoris in the 7 to 10 days preceding treadmill testing,

and an additional 4 patients had angina for the first time during this interval. The average frequency of anginal attacks was twice weekly in these 11 patients, all of whom received only nitroglycerin for relief of chest pain. No patient received beta blockers or calcium-channel antagonist drugs for treatment of chest pain. In 4 patients who were receiving beta blockers for control of arrhythmia or blood pressure, this medication was discontinued 24 to 36 hours before treadmill exercise. None of these patients had treadmill-induced ischemic S-T segment depression or angina pectoris. Of the 11 patients with angina pectoris before or after infarction, 7 had treadmill angina. Only 1 patient with treadmill angina had neither preinfarctional angina nor angina in the 7 to 10 days preceding the exercise test. Of the 8 patients with treadmill angina, 6 had S-T segment depression; an additional 7 patients had painless ischemic S-T segment depression.

Relation between pretreadmill self-efficacy and treadmill performance: To determine the extent of agreement between self-efficacy judgments and treadmill performance, efficacy scores were correlated with peak treadmill heart rates. Correlations between peak treadmill heart rate and post-treadmill self-efficacy, which approximated $r = 0.5$, were generally higher than between peak treadmill heart rate and pretreadmill self-efficacy, which approximated $r = 0.36$. After exercise testing, scores for all 5 activities and for general exertion increased significantly and were proportionately greater for running, climbing, and general exertion than for walking, sexual activity, or lifting (Fig. 1, cross-hatched portions of vertical bars).

Among patients with low self-efficacy scores before treadmill testing, those who performed well on the test exhibited proportionately larger increases in self-efficacy than those who performed less well (Fig. 2). Of the 20 patients whose pretreadmill self-efficacy scores for running 1 block were below the group mean, 12 performed relatively intense treadmill exercise and 1 of these stopped because of angina pectoris. Self-efficacy scores for running 1 block increased 285% after treadmill exercise in these 12 patients ($p < 0.005$). In contrast, the remaining 8 patients with low pretreadmill self-efficacy scores for running 1 block performed relatively less intense exercise (Fig. 2) and 4 of these 8 were stopped because of exertional angina pectoris. Self-efficacy scores for running increased 130% after treadmill exercise in these 8 patients (not significant [NS]).

Among patients with *high* self-efficacy scores before treadmill testing, those who performed well on the test sustained high values of self-efficacy (+58%), whereas self-efficacy tended to decrease (−33%) in patients who performed less well (Fig. 2). Of the 20 patients whose pretreadmill self-efficacy scores for running 1 block were above the group mean, 15 performed relatively intense treadmill exercise and none was stopped because of angina pectoris. In contrast, the remaining 5 patients of this group with high pretreadmill self-efficacy scores for running 1 block performed relatively less intense treadmill exercise (Fig. 2) and 3 of the 5 were stopped because of exertional angina pectoris.

Thus, patients in whom self-efficacy scores remained low or decreased after treadmill testing, who comprised one third (13 of 40) of the patients, accounted for 88% (7 of 8) of those with limiting angina pectoris. These patients also accounted for 54% (7 of 13) of patients with exercise-induced ischemic S-T segment depression.

Effect of counselling on self-efficacy: The additive effect on self-efficacy of counselling by a physician and a nurse is shown by the clear portions of the vertical bars in Figure 1. After counselling sessions, self-efficacy scores for sexual activity, lifting, and general exertion increased significantly above the treadmill baseline with the greatest proportional increases being observed in the areas of sexual activity and lifting.

The combined effect of treadmill testing and counselling on subsequent physical activity at home was evaluated by comparing the activity logs completed by 18 patients before and after exercise testing and counselling. The highest mean level of physical activity for which these patients expressed 100% confidence before the testing and counselling session corresponded to walking 4 to 5 blocks, running <1 block, climbing 1 to 2 flights of stairs, engaging in sexual intercourse <5 minutes, and lifting <40 pounds (18 kg). Before exercise

FIGURE 2. Self-efficacy (running 1 block) before (SE_1) and after (SE_3) treadmill exercise and counselling: relation to peak treadmill heart rate (beats/min [BPM]) and work load (mets). Note that 7 of the 8 patients who had treadmill-induced angina pectoris (numbers in parentheses) demonstrated persistently low or decreasing self-efficacy ratings after treadmill testing and counselling (13 patients).

testing and counselling sessions, these patients reported walking an average of 29.1 ± 19.5 minutes a day, attaining a peak heart rate of 78 ± 10 beats/min (Fig. 3). In the week after the testing and counselling, patients reported walking an average of 44.4 ± 27.3 minutes daily, attaining a peak heart rate of 87 ± 14 beats/min. The mean increase in duration of walking and in peak heart rate were both statistically significant ($p < 0.005$).

Self-efficacy as a predictor of subsequent physical activity at home: Changes in self-efficacy scores after exercise testing and counselling predicted subsequent changes in self-reported activity levels. For example, changes in self-efficacy scores for leg work were significantly correlated with self-reported mean heart rate and with average duration of self-reported leg exercise during home activity: $r = 0.53$ and 0.34 (both $p < 0.01$). In contrast, values of peak treadmill heart rate were insignificantly correlated with self-reported mean heart rate and with the average duration of self-reported leg exercise during home activity: $r = 0.30$ and 0.08, respectively.

Discussion

In the present study, self-efficacy judgments proved to be an important link between functional status and physical performance: these judgments predicted how well patients performed on the test and were in turn modified by the test performance. These modified judgments were more accurate predictors of subsequent home activity than was the treadmill performance itself. Findings of the present study have 2 important clinical implications:

1. Patients appear to realistically appraise their capacity to perform various physical activities even before carrying out these activities. For example, the 20 patients who expressed low self-efficacy for running 1 block before treadmill testing demonstrated a lower treadmill heart rate and work load than the 20 patients who expressed high self-efficacy before treadmill testing (Fig. 2). Compared with patients with high self-efficacy scores before treadmill exercise, these 20 patients demonstrated a higher incidence of angina pectoris before infarction and after infarction. Even a subtle degree of angina pectoris, which caused patients no significant distress, appeared to lower their expectations regarding their pending exercise test performance.

2. Patients' judgments regarding their capacity for physical effort become more congruent with their demonstrated exercise capacity after safe completion of treadmill exercise. The relation between self-efficacy and angina pectoris was further strengthened by completion of treadmill exercise: whereas the 20 patients with low self-efficacy before treadmill testing accounted for 5 of 8 patients with treadmill angina, the 13 patients with low or decreasing self-efficacy *after* treadmill exercise accounted for 7 of the 8 patients with treadmill angina. It is not surprising that the strength of association between angina and self-efficacy increased after treadmill exercise, since none of the 40 patients of the study had, before their 3-week test, performed exercise as strenuous as that of treadmill testing. The 13 patients whose self-efficacy scores remained low or decreased after treadmill testing also demonstrated a lower peak treadmill heart rate and work load than the 27 patients whose self-efficacy scores increased from initially low values or remained high. We have previously noted a diminished peak treadmill heart rate and work load in post-MI patients with treadmill-induced angina pectoris.[12]

The close relation noted in our patients between treadmill performance and changes in self-efficacy underscores the importance of such testing as a nonverbal teaching technique, for self-efficacy judgments were made immediately after the test and before the physician and nurse had explained the test results. We cannot exclude the possibility that self-efficacy scores might have increased significantly in patients completing the questionnaires on 3 occasions within a 3-hour period without undergoing exercise testing or counselling. However, significant increases in self-efficacy resulting from repeated administration of the self-efficacy questionnaire have not been noted in previous studies.[8] Self-efficacy theory predicts that direct experience of leg work under safe conditions should preferentially alter self-efficacy for activities similar to the exercise itself, while authoritative persuasion by a physician or nurse should preferentially alter self-efficacy for activities such as lifting and sexual intercourse which are dissimilar to exercise testing. The results of the present study are in keeping with these general principles: performing large muscle dynamic exercise on the treadmill increases self-efficacy for similar tasks such as walking, running, and stair climbing more than for dissimilar tasks such as static effort or sexual intercourse. Further, self-efficacy increased to a greater extent for activities such as jogging, which patients had not yet attempted, than for activity such as walking, which they had already carried out before exercise testing.

Counselling by a physician and nurse exerted the greatest influence on self-efficacy for activities such as lifting and sexual intercourse, which are dissimilar to exercise testing. Self-efficacy for a particular activity was thus shaped by an individual's past success in per-

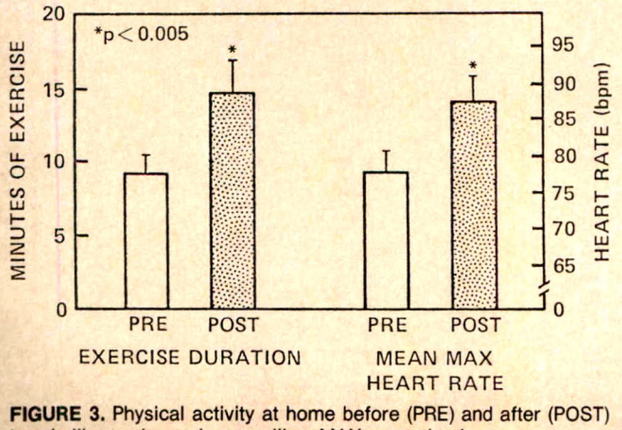

FIGURE 3. Physical activity at home before (PRE) and after (POST) treadmill exercise and counselling. MAX = maximal.

forming that activity or ones similar to it, and by the amount of encouragement given by a respected and credible authority figure.[13] Counselling appears to be an important technique for reinforcing changes in self-efficacy resulting from exercise testing and for generalizing these changes to other physical activities. Physicians should not assume that exercise test performance alone, without counselling with regard to specific activities, will enhance patients' activity levels or speed their resumption of usual physical activities such as return to work.

Exercise testing soon after MI has found wide usage for evaluating prognosis[14,15] and providing individualized guidelines for physical activity.[16] In contrast, the potential of such testing to shape patients' expectations and attitudes regarding their capacity for physical activity has been largely overlooked. The present study suggests that exercise testing and counselling not only influence patients' expectations, but that the expectations themselves mirror the patients' cardiovascular performance. Further, patients' actual performance of physical activity in their home environment was well correlated with their self-efficacy after treadmill testing and counselling. In fact, self-efficacy after treadmill and counselling was superior to peak treadmill heart rate in predicting the duration and intensity of physical activity in the home environment.

Because the present study was designed to examine the relation between perception (self-efficacy) and performance (physical activity in the patient's usual environment), no formal attempt was made to influence patients' physical activity at home. Specifically, in the counselling sessions we did not specify to patients which types of physical activities to be carried out in their usual environment were "appropriate," although for reasons of safety we discouraged any activity during which the "clearance" heart rate would be exceeded. The study was not designed to document the efficacy of physical conditioning commencing soon after MI for enhancing functional capacity. We found in a prior study that patients who had undergone exercise testing soon after MI were relatively active during the next 8 weeks—perhaps as a result of the increased confidence they gained in their capacity for physical effort.[16] The modest but significant increase in the duration of physical activity at home and in the average peak heart rate observed in the present study are in keeping with this prior experience. Further study is required to establish the extent to which the "spontaneous" increases in the duration and intensity of home activity observed in the present study can be augmented by formal exercise conditioning.

A note of caution is appropriate regarding the extrapolation of these results to patients with lower socioeconomic status or greater cardiovascular impairment. The patients of the present study constitute approximately 60% of men aged ≤70 years who are alive 21 days after hospital admission for treatment of MI. The first year mortality rate of these patients undergoing exercise testing is <2%.[17] Approximately two thirds of these patients are classified as white collar and more than 90% of those aged ≤60 years are employed at the time of infarction. Whether the relation between self-efficacy and cardiovascular capacity observed in the present study obtains in older, sicker, and more socially disadvantaged patient populations remains to be demonstrated.

Treadmill Walking Protocol for the Diagnostic Evaluation And Exercise Programming of Cardiac Patients

LENORE R. ZOHMAN, MD, JEFFREY L. YOUNG, MA, and ALBERT A. KATTUS, MD

This study (1) describes a treadmill walking protocol which has been used safely in over 40,000 tests since 1960, (2) presents normative data on oxygen consumption ($\dot{V}O_2$) so that it may be determined from work load without direct measurement, and (3) demonstrates simple techniques for early activity prescription or later therapeutic walking programs for patients after myocardial infarction (MI) based on this treadmill test. Normative data are presented on 131 subjects. There were no significant differences in $\dot{V}O_2$ values at the various work loads dependent on age, gender, fitness level, familiarity with the test procedure, clinical status, or the presence or absence of beta blockade. The protocol was then applied in cardiac rehabilitation of 25 patients. As a low level test, in 2 to 9 minutes patients attained 56 to 83% of age-predicted maximal heart rate. The translation of these data into early activity guidelines is shown. For a walking program, the maximal speed attained at 10% grade on the treadmill when walked *on level ground* put patients in the target heart rate zone for cardiovascular conditioning.

Several treadmill exercise test protocols have been described during the past 15 years, each offering special advantages under particular circumstances according to its proponents.[1–4] The Bruce protocol,[6] which has been in use since at least 1964, is probably the most familiar and the most popular because it offers a rapid and safe exercise pattern for which normal standards for blood pressure and heart rate as well as oxygen consumption ($\dot{V}O_2$) have been presented. The Bruce tables for normal or cardiac patients enable the tester to estimate maximal $\dot{V}O_2$ from work load attained or from minutes of treadmill exercise (without direct measurement), and the Bruce nomograms permit derivation of functional aerobic impairment from this information.

However, since the Bruce protocol requires changes in both speed and grade between work loads, it is sometimes difficult for patients to accommodate to the large work increments. At times in deconditioned patients, the peripheral musculature may fatigue before the central circulation can be adequately challenged. It is also more difficult for a lone technician working with a physician to change both speed and grade at just the right time, to take blood pressure, and to collect gases, while making sure the patient is not thrown off balance. In addition, the Bruce test is a walk-jog test with a variable transition point from walking to jogging among subjects.[6] This results in a variety of mechanical efficiencies at stage III (sixth to ninth minute) with varying oxygen costs at this work load so that the Bruce "table" values for $\dot{V}O_2$ may not always hold. Furthermore, during jogging, the electrocardiogram may be distorted by artifacts resulting not only from muscle movement but also from foot impact.

This report (1) evaluates a progressive treadmill *walking* protocol first reported by one of us (AAK) in 1968[7] and used safely in its present form by the authors in over 40,000 tests since 1960; (2) presents normative data on $\dot{V}O_2$ so that it may be determined from work load without direct measurement; and (3) demonstrates simple techniques for activity prescription after myocardial infarction (MI) or therapeutic walking programs based on this treadmill test.

Section I of this report, describing the test itself, is based on the data from 131 subjects who had exercise tests with $\dot{V}O_2$ measurements in the Exercise Laboratory at Montefiore Hospital in New York City during an 8-month period. Section II describes the use of this walking protocol (1) as a low-level test for 12 hospitalized patients recovering from MI, upon which to base activity prescription after discharge, and (2) for direct prescription of a walking program for 13 other patients more than 6 months after myocardial infarction.

Section I

Patients

Among the 131 individuals included, 117 were men and 14 were women (mean age 52 ± 10 years; range 32 to 69). After the testing procedure the patients were divided into 4 clinical groups as follows. *Group I—Normal:* This group contained 20 persons with no history of coronary artery disease and no risk factors. All were totally asymptomatic and all had negative, nonischemic exercise stress tests. *Group II—Post-MI:* This group consisted of 49 persons, all of whom had recovered more than 3 months earlier from documented acute MI corroborated by electrocardiography or enzyme studies, or both. *Group III—Coronary artery disease without MI:* Among the 17 persons in this group, 4 had significant coronary artery disease verified on angiography by the finding of >70% stenosis (diameter reduction) in >1 coronary artery. The others had ischemic exercise electrocardiograms and thallium scans with an average probability of coronary artery disease of 98 ± 1%.[8] *Group IV—Possible coronary disease:* This group was composed of 45 persons who presented with atypical or nonanginal chest discomfort or pain and who had equivocal, inconclusive, or nonischemic exercise stress test results. They had an average probability of coronary disease of 22 ± 13%.[8]

Methods

Test procedure: All treadmill tests were carried out at least 2 hours after a light meal in an environmental chamber at 19°C and 54% relative humidity. After history taking and cardiologic examination, a 12-lead supine resting electrocardiogram was recorded. Thereafter, the exercise test was performed on a Quinton 18-54 model treadmill. Holding onto the handrail was not permitted. The test protocol is shown in Figure 1. No patient, regardless of size, found it necessary to jog at any stage he or she could carry out. Leads V_5 and aVF were monitored, with 5 to 10 second tracings recorded each minute on a Hewlett-Packard 1500 A electrocardiograph machine. Left-arm cuff blood pressures were measured every minute and phase V (disappearance of sound) was taken as the diastolic blood pressure. Patients reported symptoms every 30 seconds according to a 1+ to 4+ grading system.

Endpoints: Patients exercised to either clinical or physiologic maximal effort. Physiologic maximum (all-out effort) was considered to be the point at which heart rate or blood pressure failed to increase with increasing work loads or where there were other manifestations of insufficient cardiac output and circulatory compromise such as ataxic gait, localized or generalized pallor indicative of cutaneous vasoconstriction, or nausea. Patients were not stopped at any predetermined heart rate. Clinical maximum was taken to be the point of 3+ symptoms. At no time did patients proceed to the 4+ level. Waxing and waning discomfort early in the test was not considered to be 1+ until it became constant although mild.

Although the test endpoints were usually either clinical or physiologic maximum, on occasion patients were stopped before reaching these levels by the testing physician if the diastolic blood pressure was >130 mm Hg, 2 or more premature ventricular complexes appeared in a row on more than 2 occasions, any sustained arrhythmia or bigeminy occurred, there was intermittent or sustained bundle branch block, or extreme generalized fatigue was described.

Interpretation of test results: The stress test was considered ischemic if the tracing demonstrated >1.0 mm horizontal or downsloping S-T segment depression in the majority of complexes in a lead or if there was >2.0 mm of upsloping S-T depression 0.08 second after the J point. Tests were considered "borderline" if there was less S-T depression than this or if the requisite amount of S-T depression was not a consistent finding on all the complexes in 1 lead. Tests were labelled "inconclusive" if the patient was unable to achieve 85% of the predicted maximal heart rate, (Scandinavian-Myrtle Beach tables) or if the electrocardiogram was uninterpretable due to conduction disturbances, ventricular hypertrophy, or medication.

The blood pressure response was considered adaptive if systolic blood pressure rose by 8 to 10 mm Hg/MET. The diastolic response was considered excessive if there was an increase >15 mm Hg or if the pressure, which may initially have been elevated, failed to decrease and remained >100 mm Hg throughout the procedure. All stress test results were read initially by the testing cardiologist and subsequently by an-

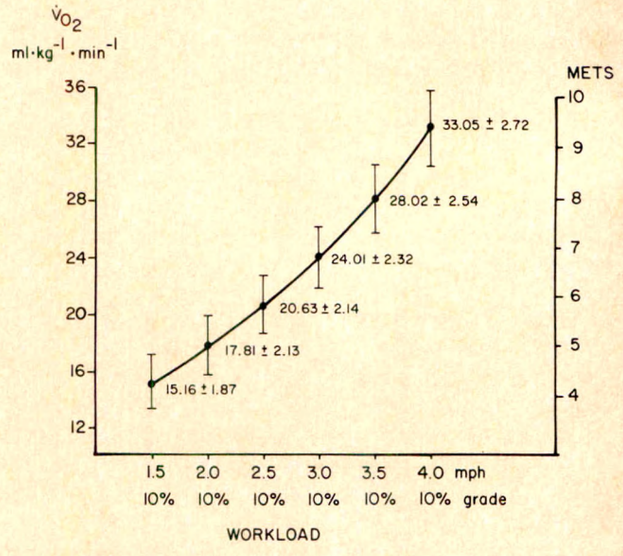

FIGURE 2. Oxygen consumption of the treadmill walking protocol. $\dot{V}O_2$ ml·kg^{-1}·min^{-1} = oxygen consumption expressed as milliliters of oxygen consumed per kilogram of body weight per minute; METS = metabolic unit, that is, oxygen consumption at rest, neither basal nor asleep: 1 MET = approximately 3.5 ml·kg^{-1}·min^{-1}. Values are presented ±1 standard deviation. MET level at 1.5 mph = 4.3; 2.0 mph = 5.1; 2.5 mph = 5.9; 3.0 mph = 6.9; 3.5 mph = 8.0; 4.0 mph = 9.4.

other attending cardiologist who interpreted the tests blindly. A third cardiologist was needed infrequently to adjudicate disagreements.

Respiratory gas measurements: Gas collections were carried out by having the patient breathe through a low resistance Otis-McKerrow valve with expired air channelled through 1.5-inch internal diameter tubing into evacuated Douglas bags. The bags were immediately analyzed for oxygen and carbon dioxide content with a Beckman E-2 oxygen analyzer and a Godart thermal gas analyzer, respectively. Both instruments had been calibrated with gases of known composition which had been verified by repeated micro-Scholander analysis. Expired volume was measured using an American gas meter, previously calibrated against a Tissot spirometer. Minute ventilation, oxygen consumption, and carbon dioxide production (STPD) were calculated.

Statistical Analyses

Values obtained for blood pressure, heart rate, and electrocardiographic wave form for this protocol are not presented in this report. Patients were classified retrospectively into clinical groups as described under Patient Population including these results. Oxygen consumption data were analyzed in depth, however, since maximal $\dot{V}O_2$ provides the best evidence of the functional severity of the impairment among cardiac patients.

Oxygen consumption values at a given work load were included in the analyses only if the following criteria were met: (1) the gas collections were technically completely satisfactory (noseclip tight, no air leaks at the mouth, accurate timing of the collection, analysis carried out immediately, meters functioning accurately and with stability); (2) the patient exercised at a given stage for the full 3 minutes; (3) the $\dot{V}O_2$ for that stage was not the maximal $\dot{V}O_2$; (4) the highest $\dot{V}O_2$ used was collected at least 1 minute before cessation of exercise. By this means, all $\dot{V}O_2$ measurements included were submaximal, and probably "steady state" for the work load.

Oxygen consumption data at the various work loads were compared using analysis of variance (ANOVA) and tests of multiple comparison when necessary (1) among subjects of different ages, (2) among men versus women, (3) for exercisers versus sedentary adults, (4) for those who had previous treadmill tests and those who did not, and (5) among persons receiving, versus those not receiving, beta-blocking drugs.

Thereafter, data were reanalyzed according to the 4 clinical groups described under Patient Population, using the same techniques.

The final compilation pooled data from all subjects to derive $\dot{V}O_2$ values for work load and includes the data for normal subjects and patients aged 30 to 69 years, men and women of varying fitness levels, either receiving or not receiving beta blockade.

Results

Neither morbidity nor mortality resulted from the 131 stress tests. There were no significant differences in $\dot{V}O_2$ values at the various work loads dependent on gender, fitness level, familiarity with the testing procedure, or presence versus absence of beta blockade.

When stratified for work load, age had no significant effect on $\dot{V}O_2$ except for a difference of borderline significance at 4.0 mph/10% grade ($p < 0.05$). At this work load, mean $\dot{V}O_2$ varied at most by 2.9 $ml \cdot kg^{-1} \cdot min^{-1}$.

When examining $\dot{V}O_2$ in the different clinical groups, group differences were suggested only at work loads of 2.0 and 3.0 mph/10% grade (each $p < 0.05$). At 2.0 mph/10% grade, the mean $\dot{V}O_2$ ranged from 16.6 ± 1.5 (Group III) to 18.7 ± 2.4 $ml \cdot kg^{-1} \cdot min^{-1}$ (Group IV). At 3.0 mph/10% grade, results were similar, with a mean $\dot{V}O_2$ of 22.7 ± 1.3 for Group III and 24.8 ± 2.0 for Group IV.

None of these differences between groups exceeded the 10% interindividual variation reported by Wyndham et al[9] for subjects performing walking tasks. Therefore, although of borderline statistical significance, these differences are within the range of individual variation and thus have no clinical relevance. Since these comparisons failed to show meaningful differences according to age, sex, familiarity with the test, medication, or clinical diagnosis between Groups I to IV, data for oxygen consumption were pooled resulting in the normative data shown in Figure 2.

Section II

Use of the Treadmill Walking Protocol in Activity and Exercise Prescription

To evaluate the usefulness of this protocol as the basis for exercise programming, 12 patients had a low-level exercise test at 8 to 23 days after MI and 13 others were evaluated more than 6 months after MI before entering exercise training programs. Characteristics of the patients are listed in Tables I and II.

Procedure: Patients recovering from MI who had a low-level test followed the same protocol as that depicted in Figure 1, beginning at 1.5 mph/10% grade. Exercise was continued until the appearance of 1 to 2+ symptoms, or an arbitrary endpoint at approximately 70% of the age-predicted maximal heart rate. Patients receiving beta blockers followed the same protocol.

The walking test protocol was also carried out in 13 other patients who had sustained MI more than 6 months earlier to either a 3+ clinical or physiologic maximal endpoint. Thereafter, 46 days later (average value) these 13 patients were monitored during *level* treadmill walking, starting at 1.5 mph and increasing 0.5 mph every 3 minutes until the patient achieved 85% of the maximal heart rate attained on the previous stress test. Patients receiving beta blockers had both the walking test and the monitoring on level walking on the same dose of medication. Since exercise incurring a target heart rate of 70 to 85% of maximal attained heart rate is accepted as the appropriate intensity of effort that will result in cardiovascular conditioning, the relation between maximal speed walked on the stress test (at 10% grade) and the heart rate resulting from walking at the same treadmill speed on the flat was examined.

Results: Table I shows that within 2 to 9 minutes the 12 recovering MI patients reached 56 to 83% of their age-predicted maximal heart rates, levels appropriate for a submaximal performance test carried out soon after MI. Eight tests were discontinued by the testing physician at 70% of maximal heart rate and 4 were discontinued because of symptoms. No detrimental effects resulted from any test: 4 demonstrated ischemia by electrocardiogram, 1 was borderline, and the other 7 were negative at these submaximal levels.

* Patients had the maximal treadmill test and the subsequent monitoring with the same dose of beta blockers.
EST = exercise stress test; HR = heart rate; prop = propranolol; nad = nadolol; THR = target heart rate.

Table II examines the relation between the heart rate attained on level walking and 70 to 85% of the maximal heart rate achieved during grade walking at the same speed in the 13 patients with healed MI. That is, in this table we attempt to determine whether advising the patient to walk on the level ground at the maximal speed attained during treadmill walking at a 10% grade would put him or her in the target heart rate zone for exercise training. Eight of the 13 patients had heart rates within their target range when exercise was prescribed by this method. The other 5 patients were below their target rate. No patient exceeded the target range using this method.

Although the data for the patients receiving beta blockers in both Tables I and II seem essentially the same as the data for those not taking propranolol, too few patients were examined (11 of 25) to make statistical comparisons. These results suggest, however, that this walking protocol is useful both for providing activity guidelines upon hospital discharge after infarction, and for exercise programming later on, regardless of whether the patient is receiving beta blockers.

Discussion

The data presented describe the work load and energy cost of a treadmill walking protocol useful for both diagnostic exercise testing and for activity and exercise prescription for either cardiac patients or normal persons. Measurements were made during treadmill tests done for clinical purposes. Although 20 persons were normal subjects seeking exercise advice, and 45 had a low probability of coronary artery disease, the remaining 66 were coronary heart disease patients. The data are thus representative of office stress testing practice with a prevalence of disease of approximately 50%.

Since the procedure described is entirely a walking test, $\dot{V}O_2$ values follow a smooth curve, rising approximately 1.0 MET/stage from about 4.0 METS at 1.5 mph to 9.0 METS at 4.0 mph at 10% grade. Since there is no transition point between walking and jogging using this protocol, variations in $\dot{V}O_2$ dependent on biomechanical factors were avoided. Astrand (personal communication) has found that at stage III of the Bruce test, oxygen consumption is the same if one runs supported by the handrail or one walks without holding on (Fig. 3). The

OXYGEN UPTAKE $L \cdot min^{-1}$	2.9	2.2	3.2	2.9
HEART RATE Beats $\cdot min^{-1}$	155	138	168	158

Subject's body weight 75 kg

FIGURE 3. Treadmill text (3.4 mph, 14% grade). (Courtesy of Professor Per Olof Astrand, Stockholm, Sweden.)

normative data presented for our treadmill walking test is also essentially the same (within 1 standard deviation) of that which can be derived arithmetically from the formulae and nomograms of Workman and Armstrong.[10,11]

Barnard et al[12] measured the energy cost of this test at higher work loads, that is, when speed remained at 4.0 mph but grade was increased beyond 10% in 4% increments. The MET levels then jumped to approximately 12, 14, and 15 METS at successive stages and $\dot{V}O_2$ values were 43 ± 1 at 14% grade, 50 ± 2 at 18%, and 54 ± 2 $ml \cdot kg^{-1} \cdot min^{-1}$ at 22%, respectively. This test may also be used for fit subjects beginning at 2.0 mph, 10% grade, and progressing to 3.0 mph, 10%, and 4.0 mph, 10%, in 3-minute stages without the intervening work loads, with essentially the same $\dot{V}O_2$ values for work load we have reported, by making use of the figures of Barnard et al.

The $\dot{V}O_2$ values presented here apply only when the person has achieved steady-state conditions (at the end of the stage) and are not precise enough (although clinically usable) for defining maximal performance levels, at which time $\dot{V}O_2$ may no longer be increasing linearly with work load.

Within these guidelines, however, it is appropriate to estimate $\dot{V}O_2$ from the work load reached when patients exercise on the treadmill using this protocol, hence the MET level attainable near-maximally and the MET level at which ischemia becomes evident. Knowledge of MET level at ischemia or near-maximal effort and heart rate at these levels provides the physician with the information needed to prescribe home activity on hospital discharge, rehabilitative conditioning exercise, or an exercise training program.

Use of the Treadmill Walking Test as a Low-Level Test in Early Cardiac Rehabilitation

In our experience, some of the early low-intensity treadmill protocols such as that proposed by Halpenny[13] and expanded by Sivarajan and Bruce,[14] or the graded exercise test protocol of Sheffield,[2] fatigue the patient before an adequate cardiovascular challenge can be presented at 70% of maximal heart rate. Patients are exercising at approximately the 4 MET level only after 9 to 12 minutes of walking according to these protocols, yet some of our patients had to reach the 6 MET level before attaining 70% of maximal heart rate. Extending the duration of the low level protocol beyond 9 to 12 minutes to reach a 6 MET level can sometimes prove exhausting to deconditioned patients. The treadmill walking protocol described here may provide the needed information within 3 to 6 minutes. If the patient is unable to walk at 10% grade for 3 minutes, the test may be stopped and, after a 10-minute rest period, it may be begun again at 1.5 mph, level walking or 5% grade.

Since *maximal* beta blockade may force recovering MI patients to do heavy exercise before reaching 70% of their age-predicted heart rate values, and since beta blockade does not alter oxygen consumption, we limit the low level test to the achievement of approximately

TABLE III Energy Cost (METS) of Various Activities for Convalescent Cardiac Patients*

	Self-Care Activities
1.2	Sitting quietly
1.1–1.5	Standing quietly
1.5–2.0	Eating, conversation
1.5–2.0	Washing hands and face, brushing teeth
1.6–3.4	Washing and dressing, moving about (women)
2.6–4.3	Washing and dressing, moving about (men)
3.7–4.4	Showering
	Diversional Activities
1.5–2.0	Knitting, sewing, listening to radio
1.5–2.0	Playing cards, watching TV
1.8–2.8	Playing a musical instrument—piano, strings
2.8–4.0	Playing organ or drums
2.0–3.0	Light woodworking
	Light Work at Home
1.5–1.9	Office work at a desk, standing, moving about
1.5–2.0	Typing and using office business machines
1.2–3.6	Driving (depends on traffic)
3.1–4.2	Gardening—weeding, using trowel, edging borders, raking
5.3–5.7	Cutting hedges, mowing lawn
	Housework
1.6–2.0	Sweeping floors, preparing vegetables
2.1–3.0	Preparing and serving a meal, washing dishes
2.1–3.0	Dusting, polishing, ironing
3.1–4.1	Bedmaking, vacuuming, shopping (light load)
4.2–5.3	Scrubbing floors, shopping (heavy load)
	Physical Exercise
2.6–2.7	Walking 2.0 mph
3.1–3.2	Walking 2.5 mph
3.6–3.8	Walking 3.0 mph
4.1–4.4	Walking 3.5 mph
2.0–3.4	Light calisthenics (trunk bends, knee raises, arm circles)
2.3–4.4	Bowling
2.0–3.0	Golf with power cart
4.0–7.0	Golf pulling cart
2.5–5.0	Volleyball
4.0–5.0	Table tennis
4.0–5.0	Climbing down stairs
6.0–8.0	Climbing up stairs
4.0–6.0	Sexual activity with familiar partner

* Rest, supine but not basal equals 1.0 MET (metabolic unit). These values are based on average weights of 55 kg (female) and 65 kg (male). All values are approximate since speed of performing activity, proficiency, climatic conditions, and emotional pressure can induce significant variation.

60% of the maximal predicted $\dot{V}O_2$ consumption for age. Sixty to 80% of an individual's maximal $\dot{V}O_2$ is equivalent to 70 to 85% of the maximal heart rate.[15] For persons of average fitness tested using this walking protocol, the 60% $\dot{V}O_2$ level occurs at approximately 2.5 mph/10% grade for those below 50 years of age and at 2.0 mph/10% grade for those over age 50 years. Work load can then serve as the arbitrary termination point for the low-level test done with beta blockers, unless clinical indications dictate to the contrary.

Depending on whether ischemia resulted from the low-level test and whether the physician permits out-of-hospital activities which incur ischemia, the MET level attained on the test is easily equated to cardiac rehabilitation activities (Table III).

Use of the Treadmill Walking Test for Exercise Training Programming

Physical conditioning and exercise training are usually based on a maximal treadmill test carried out at least 6 weeks after MI, although DeBusk et al[16] have begun conditioning patients as early as 3 weeks after MI with the exercise recommendation based on the symptom-limited treadmill test. The appropriate exercise prescription for training involves aerobic exercise (rhythmic, repetitive, continuous) carried out at 70 to 85% of maximal attainable heart rate on the treadmill test for 20 to 30 minutes 3 times weekly, preceded by a warm-up and followed by a cool-down period.[17,18]

Brisk walking can result in a significant training effect on oxygen consumption, blood pressure, and heart rate, as well as favorable changes in body composition (reduction in total weight and percent fat) in 20 weeks.[19] If the individual also carries a 3 to 6 kg (6.6 to 13.2 lb) load in a backpack and walks 30 minutes daily, 5 days weekly at 5 km/h (approximately 3.0 mph), as in the study of Shoenfeld et al[20] in Israel, aerobic capacity can be improved by 15 to 32% in only 3 weeks. Walking offers the advantages of fewer orthopedic problems than jogging, a lower dropout rate (25% versus 40% in most types of training activities), and is slow enough to permit camaraderie and conversation en route.[19]

There have been differences of opinion as to whether treadmill information can be extrapolated to ordinary ambulatory locomotion. By evaluation of the biomechanics involved, Ingen Schenau[21] presented convincing arguments that there is no fundamental mechanical difference between treadmill and fixed surface locomotion; hence our results, although obtained using treadmill training, may be extrapolated to walking outdoors, at least on smooth walking surfaces.

New Insights

Toshiba SSH-40A Ultrasound Scanner
The Complete Cardiac Lab.

How do you measure commitment? With words? Toshiba prefers to have the products make the point. Newest proof: the Toshiba SSH-40A Cardiac Ultrasound Laboratory, a vivid example of our commitment to echocardiographic diagnostics.

Clinical versatility is the watchword for the SSH-40A. It means independent or simultaneous display of 2-D echocardiograms, M-Mode and Doppler images for faster, more complete diagnosis. It means you can scan with various probes for the best image quality in all patient sizes and specialized procedures. Perform two dimensional, multigate array Doppler flow studies and perform all cardiac function computations instantly.

Image quality? Startling. Low level echoes contain the most significant diagnostic information. The SSH-40A captures and displays them with a unique, low-noise digital system: dual microprocessors and more memory than any ultrasound instrument. Plus the powerful Digital Scan Processor provides optimum control over image quality.

Such insights, frankly, defy words. That's why we're eager to provide you with a demonstration of the SSH-40A's powerful capabilities. Then you can complete the picture yourself.

Please see the reverse side for further information.

GLOBAL IMAGING SPECIALI

New Insights

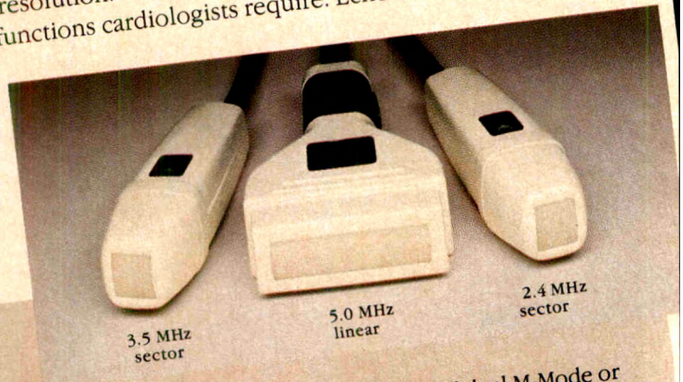
HIBA SSH-40A CARDIAC ULTRASOUND LABORATORY.

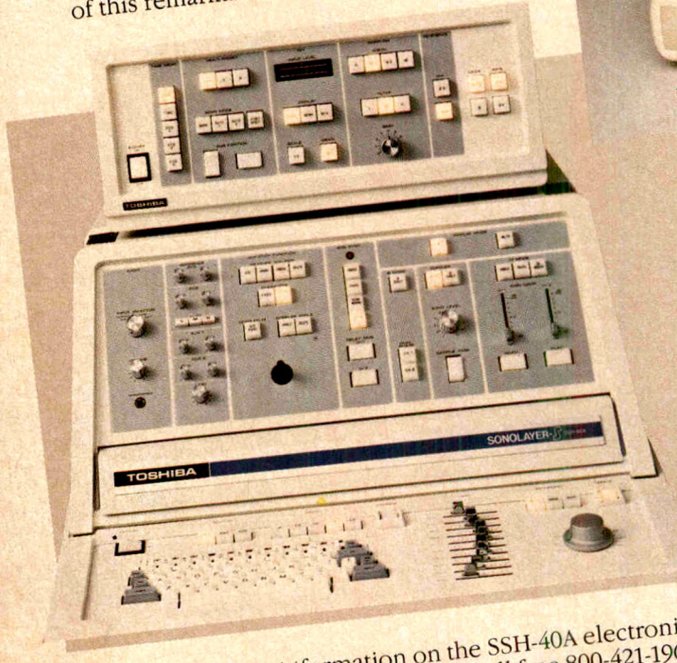
The Toshiba SSH-40A is a complete cardiac ultrasound laboratory that combines clinical versatility, superior image quality and powerful digital scan processing to provide a host of features for new insights into cardiac diagnoses.

The SSH-40A is available with a standard 3.5 MHz probe and optional 5 MHz linear scan probe and 2.4 MHz sector scan probe to enable accurate examinations of all patients, from neonates to adults. All pertinent image and exam data, including results from computations, can be displayed. And the unique two dimensional multigate array Doppler capability enables the operator to perform flow studies, to display frequency spectrum from the digital FFT analyzer and to compute flow rate, velocity and other cardiac function data. Extensive computational algorithms are on-line to ensure fast, accurate analyses.

Superb image quality results from the advanced scanning technology incorporated in the SSH-40A. A new receiver design and a new digital scan processor provide optimized image quality with clearly defined edge differentiation and excellent tissue differentiations. A faithful display of low level echoes provides excellent gray scale resolution.

The SSH-40A delivers the image processing functions cardiologists require. Echo enhancement, post processing and other echo processing operations, synchronous freezing of two phases of a cardiac cycle, slow motion display and measurement of distances and areas on frozen images are all well within the range of this remarkable system's capabilities.





- Simultaneous 2-D imaging and dual M-Mode or Doppler operation ensures more exact correlation, faster diagnosis and state-of-the-art performance.
- Cardiac function (SV, EF, FS, CO and others), area, circumference, slope and distance can be computed at the touch of a keyboard, thanks to a selection of stored algorithms.
- Simultaneous display of two images, strobed from two selected points on the ECG cycle, allows detection of abnormal wall motion.
- Comprehensive exam data display permits date, time, frequency and patient data and image annotation to be included for more complete patient records.

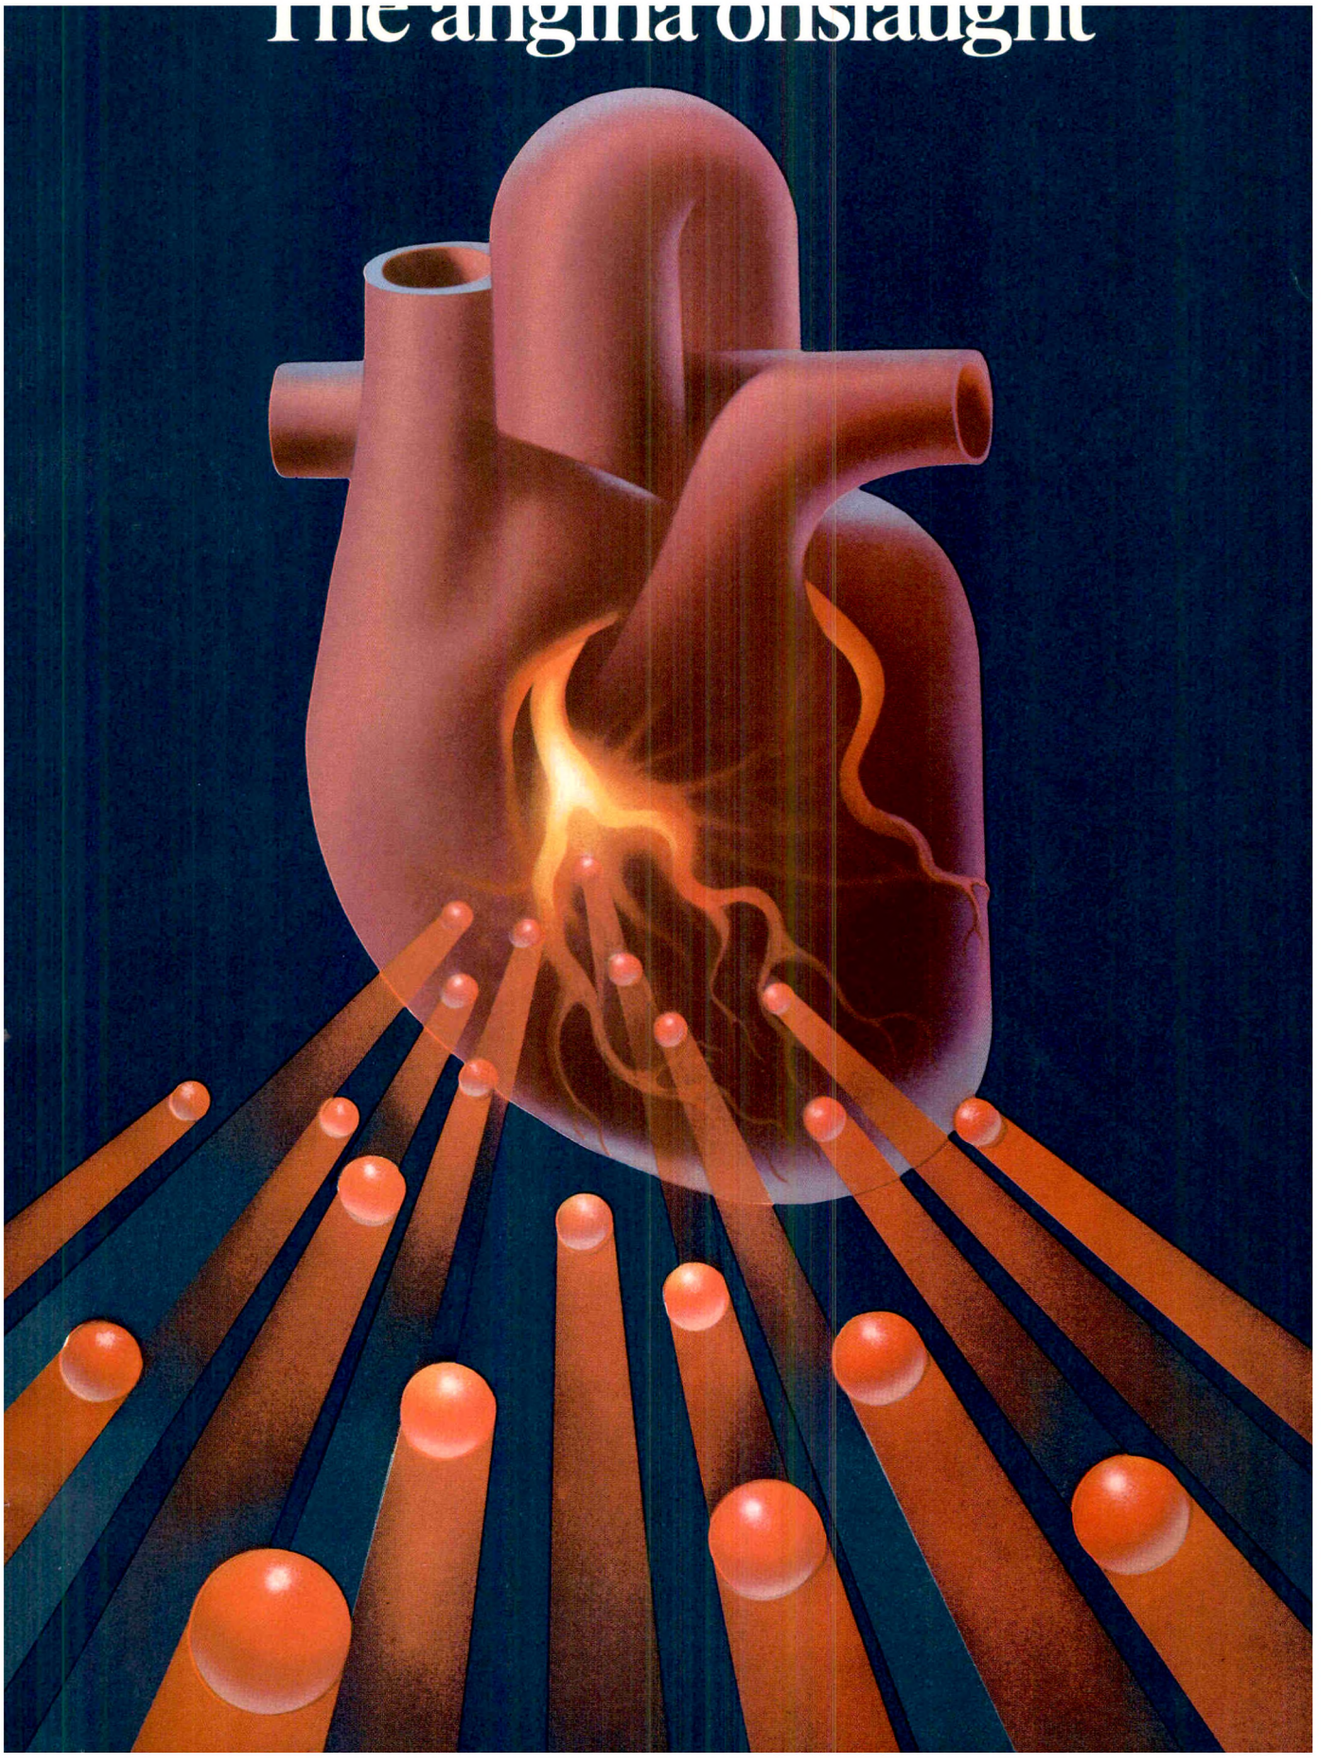
The angina onslaught



The angina shield:
CORGARD®
(nadolol tablets)

SQUIBB®

Reliable 24-hour-a-day protection...

Physical exertion, emotional strain, and the unexpected crises of daily life — these can unleash an anginal attack at any time. So it's important to be certain that your patients are protected continuously. Unlike other beta-blockers, Corgard provides this protection around the clock with a once-daily dose — reducing the anginal attack rate, increasing work capacity, and decreasing the dependence on nitroglycerin.

with convenient once-a-day dosage

A single daily dose of Corgard controls angina all day, every day. And since Corgard is associated with a low incidence of side effects,* your patients can lead more comfortable lives. An added convenience of Corgard is that it can be taken at any time of day, regardless of meals, because its absorption is not affected by food.

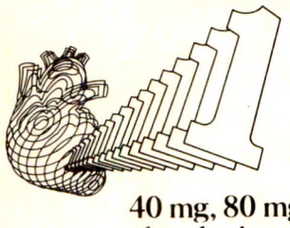
*For a full discussion of CONTRAINDICATIONS, PRECAUTIONS, ADVERSE REACTIONS, and WARNINGS, including avoidance of abrupt withdrawal, please see brief summary on next page.

CORGARD® (nadolol tablets)

The only once-a-day beta-blocker for both angina pectoris and hypertension

Please see next page for brief summary.

The only once-a-day beta-blocker for both angina pectoris and hypertension



CORGARD® (nadolol tablets)

40 mg, 80 mg, 120 mg, and 160 mg scored tablets available in a variety of bottle sizes and in Convenience Packages of 40 mg and 80 mg tablets

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure — Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System —** Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory —** Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal —** Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous —** Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System —** reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal —** mesenteric arterial thrombosis; ischemic colitis. **Hematologic —** agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic —** fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous —** reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval; see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® unit-dose packs of 100 tablets. The 40 mg and 80 mg tablets are also available in convenience packages containing 4 blister cards of 7 tablets each.

Comparative Functional and Physiologic Status of Active and Dropout Coronary Bypass Patients of a Rehabilitation Program

THAD F. WAITES, MD, EDWARD W. WATT, PhD, and GERALD F. FLETCHER, MD

To assess the benefits of regular participation in a medically supervised cardiac rehabilitation program, 22 patients who had undergone coronary artery bypass (2 groups of 11 each) were studied retrospectively. Group I (mean age 53 years) was currently enrolled in the rehabilitation program. Group II (mean age 56 years) had begun but had discontinued the program. The stated reasons for discontinuation were not medical. There was no difference in entry exercise tests, and presurgical catheterization data in both groups were comparable. Mean peak oxygen consumption (VO_2) by modified Douglas bag technique, heart rate × systolic blood pressure product, and treadmill duration time were recorded in a single testing period. Results revealed that Group I had higher peak VO_2 (30 ml/kg/min) than Group II (24) ($p < 0.005$) and greater treadmill time (11 minutes) than Group II (8) ($p < 0.01$). Nine of 11 subjects in Group I were fully employed, versus 4 of 11 in Group II ($p < 0.01$). One of 11 subjects in Group I had been rehospitalized versus 5 in Group II. None in Group I but 4 of 11 subjects in Group II smoked. Thus, based on the sampling and methodology of this study, it is concluded that coronary artery bypass patients in rehabilitation programs have greater peak VO_2 and treadmill test time, smoke less, are less often rehospitalized, and are more often fully employed than those who are not in such programs.

Coronary artery bypass surgery as an intervention for relief of myocardial ischemia is frequently utilized in the management of patients with coronary artery disease.[1] Although not universally accepted, several studies indicate that bypass surgery improves myocardial function through revascularization.[2,3] After surgery, these patients often enroll in cardiac rehabilitation programs for risk factor modification and exercise training.

It has been demonstrated that such rehabilitation programs improve many indexes of cardiopulmonary function, particularly by increasing oxygen consumption and decreasing both resting and exercise heart rate and systolic blood pressure[4] in patients with coronary artery disease. It has not been demonstrated that surgical intervention coupled with a rehabilitation program is of greater benefit than surgery alone; nor has the value of a structured versus nonstructured rehabilitation program been examined.

For the postbypass patient, does a structured, supervised cardiac rehabilitation program improve cardiopulmonary function more than an individualized, nonsupervised program? Are there other benefits of compliance in a rehabilitation program such as improved return-to-work status and major coronary risk modification?

From the Department of Medicine, Emory University School of Medicine and Georgia Baptist Medical Center, Atlanta, Georgia. Manuscript received September 28, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

Address for reprints: Gerald F. Fletcher, MD, Georgia Baptist Medical Center, 300 Boulevard NE, Atlanta, Georgia 30312.

These questions were studied by comparing 2 groups of postbypass patients. One group was enrolled in an organized rehabilitation program,[5] and the other group had begun the same program but had voluntarily dropped out.

Methods

Eighteen patients who had undergone coronary bypass were identified in the Atlanta area who had previously been regular participants (now dropouts) of the outpatient cardiac rehabilitation program. A letter explaining the retrospective study was mailed to each. In follow-up phone calls to solicit enrollment, 11 patients agreed to participate. Of those who refused, only 1 cited medical reasons (recent prostate surgery). The other 6 declined for nonmedical reasons (either travel distance or job conflict); none of these were involved in an exercise rehabilitation program elsewhere. A comparable group of 11 postbypass patients who were active in the rehabilitation program was chosen for study. All active patients were at least 9 months postbypass and had been enrolled in the rehabilitation program for at least 6 months with ≥75% attendance. The program consisted of medically supervised and individually prescribed walk or jog, calisthenic, and recreational activities. The subjects participated in these activities 3 times weekly for approximately 1 hour each session (20 to 25 minutes of walk or jog activity). Education in coronary risk factor modification (especially dietary) was an integral part of the program with both individual and group teaching both at the time of exercise testing and in the training program.

Presurgical catheterization data and angiograms of all patients were reviewed. Particular note was made of coronary artery anatomy, left ventricular end-diastolic pressure, regional wall dynamics, and ejection fraction. There was, how-

ever, no data on the presurgical exercise capacity (baseline peak oxygen consumption) of the 2 groups. Postsurgical exercise tests performed at least 3 months postoperatively for entry into the rehabilitation program were reviewed and compared, and were found comparable with regard to test duration, arrhythmias, electrocardiographic changes, heart rate, and blood pressure response.

All subjects were then scheduled for treadmill exercise testing to be done with both physiologic and hemodynamic studies. The testing procedure was explained and use of the modified Douglas bag technique was demonstrated. Testing was performed by standard protocol.[6] Precisely at the peak of exercise, a single breath sample of expired air was collected for calculation of instantaneous peak oxygen consumption.[7] (Single breath method is felt to be comparable to the Max Planck technique which correlates well with the Douglas bag technique.[8]) After a rest period, the purpose of the study was discussed further and a questionnaire was presented verbally. Exercise testing results were interpreted independently by 2 physicians. Rate-pressure product was calculated from peak heart rate in beats per minute and peak systolic blood pressure in millimeters of mercury. Standard equations[7] were used to calculate peak oxygen consumption from the expired air sample. Gas was analyzed by Beckman automatic gas analyzer (OM-11 for oxygen and LB-2 for carbon dioxide). Standard reference calibrations were performed before and after each measurement using known reference gases.

Data were analyzed by paired and nonpaired t test using 2-way tables (1 degree of freedom) and standard chi-square equations.

Results

Clinical features and physiologic and functional data acquired in the trained state for active subjects and at the same time (6-month study period) for the dropouts are seen in Tables I to V.

There was no difference in age between the active and the dropout groups (active mean = 54 years, dropout mean = 56 years); however, the age of Patient 9 in the active group (71 years) may have influenced this data to a degree, especially with the small group numbers. Body weights and heights were comparable (active mean = 80.9 kg, dropout mean = 80.6 kg and active mean = 177.2 cm, dropout mean = 176.9 cm, respectively). All active patients were male, while 3 of the dropouts were female. Peak oxygen consumption in ml/kg/min was significantly different (active mean = 30 versus inactive mean = 24) ($p < 0.005$), as well as

treadmill time (active mean = 11 minutes, inactive mean = 8 minutes) ($p < 0.001$). Peak rate-pressure products, however, were not significantly different between the groups.

Nine of 11 active patients had returned to full working status compared with only 4 of 11 dropouts ($p < 0.01$). Only 1 active patient has been hospitalized (on 2 different occasions); however, 5 of 11 dropouts have been rehospitalized for a total number of 7 rehospitalizations. All of the rehospitalizations were because of patient symptoms or circumstances and none were solely at the request of the medical-surgical team. None of the active but 4 of 11 dropout patients continued to smoke. The period of time for follow-up from start of the program was comparable between groups.

Discussion

Peak oxygen consumption correlates well with cardiovascular conditioning[9,10] and is an index of maximal cardiovascular and pulmonary function.[11] An increase in the level of habitual physical activity will increase peak oxygen consumption and revascularization resulting from bypass surgery will also increase peak oxygen consumption.[3] It has not previously been shown that bypass surgery plus an organized program of ex-

ercise improves results over bypass surgery alone; however, in this study, the active patients attained a higher mean peak oxygen consumption than those in the dropout group.

Symptom limited endpoint time on an exercise test is an indirect measurement of myocardial oxygen consumption and is an indication of myocardial blood flow.[12] Coronary bypass surgery improves myocardial blood flow and thus increases exercise test duration.[13] Previous data have shown that bypass patients further improve their time on treadmill testing after participation in an exercise program. These data also revealed improvement in treadmill duration time for bypass patients who were not regularly exercising.[14] In our study, however, the active postbypass patients were capable of a greater duration on the treadmill test than the dropouts.

The difference in oxygen consumption between our groups likely reflects a "general" training effect with larger stroke volume and cardiac output. Though the dropouts had higher peak blood pressures with testing, there was no significant difference in peak rate-pressure product between the 2 groups. Of note, 3 active and 6 dropout patients were receiving propranolol. When the work load is the same, exercise with propranolol results in lower heart rate, blood pressure, and myocardial oxygen consumption than exercise without it.[15] This greater number of patients on propranolol in the dropout (6) versus the active (3) group may therefore have accounted for some differences between groups.

General state of well-being is difficult to assess. However, based on personal interview, it seems that the active patients "felt better" than the dropouts because they were enjoying the program and the "comradeship" with other patients and staff. Of note, 4 of the 11 dropouts (Patients 2, 4, 6, and 8) (Table II) later rejoined the exercise program. Two of these 4 (Patients 4 and 6, Table II) were smokers.

Functional features of the patients are seen in Table V. None of the active patients smoked cigarettes compared with 4 of the dropouts who continued to smoke. Eight of each group had previously smoked. Peer pressure is likely a factor in this difference and the motivation to remain in a tri-weekly rehabilitation program probably also motivates them to stop cigarettes. Nine of the 11 active patients were still working. One received disability retirement before surgery; the other (age 71 years) retired at age 65. Only 4 of 11 dropouts were working. Two had physical disability retirement before surgery. The other 5 listed various health reasons (prostatism in 2, low back pain in 2, and peripheral vascular disease in 1); however, none in either group listed angina pectoris as a reason for not working. As noted, only 1 of the active versus 5 of the inactive patients were rehospitalized. All hospitalizations for the dropouts occurred 6 or more months after withdrawing from the program. In each instance the reason for rehospitalization was to have repeat coronary arteriograms because of symptoms to evaluate status of the bypass grafts. Results of studies revealed patent grafts in all subjects (Table V).

The active patients, therefore, seemed to benefit from the rehabilitation program; it is felt that compliance with the program was a significant factor. When comparing the 2 groups by presurgical data, both had comparable numbers of significantly diseased coronary arteries, left ventricular wall contraction, and end-diastolic pressure. According to operative notes, revascularization was considered complete in all cases. Postsurgical preexercise data was evaluated by comparing entry treadmill tests for the rehabilitation program. These postsurgical treadmill test results were comparable in that there was no difference between the groups with respect to duration time, electrocardiographic changes, arrhythmias, systolic blood pressure increase, or attained heart rate. There, it was felt that the groups were comparable in degree of underlying cardiovascular disease.

All patients were medically stable and motivated to begin the rehabilitation program. Though it is possible that the reason for dropping out was physical or medical inability to continue, none of the dropouts stated such reasons. In addition, there seemed to be no difference in response to the educational program between active and dropout patients. Although most had conflicts of time or distance given as reasons for dropping out, the true reasons are not clear and are likely multifactorial.

Based on the results herein discussed, coronary bypass patients in a medically supervised program have greater oxygen consumption and exercise test duration, are more often at full working status, have fewer hospital readmissions, and are less likely to smoke. These data support benefits of patient compliance in an organized cardiac rehabilitation exercise program; however, some of these beneficial effects are likely due to strong selection factors associated with entrance into and adherance to the highly structured program.

Exercise Versus Cold Temperature Stimulation During Radionuclide Cineangiography: Diagnostic Accuracy in Coronary Artery Disease

LAWRENCE J. JORDAN, BS, JEFFREY S. BORER, MD, MICHAEL ZULLO, MD, DAVID HAYES, MD, SPENCER KUBO, MD, JEFFREY W. MOSES, MD, and JOHN CARTER, MS

To assess the relative efficacy of cold temperature stimulation and bicycle exercise in inducing ischemia detectable by radionuclide cineangiography, we used both stresses to study 20 normal subjects and 54 patients with coronary artery disease (CAD), 42 of whom had not had myocardial infarction. Cold stimulation caused increases in heart rate and arterial pressure which were significantly less marked than those caused by exercise. Regional left ventricular dysfunction was induced by cold in 24 of 41 patients without previous infarction (57%) and by exercise in 34 of 42 patients (81%) ($p < 0.05$), but was absent in all normal subjects during either stress. Left ventricular ejection fraction increased during exercise in all normal subjects (average increase 18%) but decreased during cold stimulation in 12 of 20 subjects. Because of the disparate response of normal subjects to the 2 stresses, the sensitivity and specificity of radionuclide cineangiography were assessed over a wide range of ejection fraction changes independently for each stress. During exercise, at ejection fraction changes in which specificity was high, sensitivity also was high, but during cold stress, specificity was relatively poor at ejection fraction changes in which sensitivity was high, and sensitivity was relatively poor when specificity was high. During exercise, patients with anatomically severe (3-vessel, left main, proximal left anterior descending) disease manifested significantly greater reduction in ejection fraction than did patients with less severe stenoses (−10% versus −3%, $p < 0.001$); cold stimulation did not lead to similar separation (−2% versus −3%, difference was not significant). Therefore, when radionuclide cineangiography is performed, exercise is more effective than cold stress in separating normal subjects from patients with fixed obstructive CAD and in identifying patients with anatomically severe CAD.

The detection of regional and global left ventricular dysfunction induced by stress can be achieved noninvasively by the use of radionuclide cineangiography.[1–3] As a result, when employed in association with exercise, radionuclide cineangiography has proved to be a highly accurate means of diagnosis of coronary artery disease (CAD).[3] However, the sensitivity of radionuclide cineangiography during exercise in detecting CAD ranges between 82 and 98%, indicating that some cases may not be detected.[3–10] In addition, because of other physical infirmities, exercise cannot be performed by all individuals suspected of having CAD. Therefore, an alternative means of stress might be desirable if it could produce myocardial ischemia detectable by radionuclide cineangiography. Cutaneous cold stimulation has been reliable in producing evidence of myocardial ischemia.[11–14] Moreover, the method is applicable in patients who cannot perform standard exercise procedures. Therefore, in conjunction with radionuclide cineangiography, cold stimulation may be a potentially useful alternative to exercise in the detection of patients with CAD. In addition, experimental evidence suggests that results of cold stimulation may serve to complement results obtained during exercise. Ischemic heart disease

currently is viewed as the result of coronary artery obstruction comprising both fixed and dynamic components in varying proportions. Acceptance of this concept implies the potential inadequacy of exercise as an ischemic stress, particularly when the goal of evaluation is the quantification of the effects of CAD, because exercise may not reproducibly stimulate the dynamic component of coronary artery obstruction. In contrast, cold stimulation may induce coronary artery spasm at sites of atheromatous plaques,[15] thus decreasing myocardial oxygen supply, while simultaneously causing peripheral vasoconstriction which, like exercise, increases myocardial oxygen demand. Therefore, the present investigation was undertaken to assess the diagnostic efficacy of cold stimulation during radionuclide cineangiography and to compare the accuracy of this approach with that obtained when standard exercise testing is employed with radionuclide cineangiography or with electrocardiography. In addition, the relation between the intensity of cold-induced left ventricular dysfunction and the extent of anatomic obstruction of the coronary arteries was evaluated.

Methods

Studies were performed in 49 men and 5 women aged 33 to 79 years who presented at New York Hospital for evaluation of known or suspected CAD. Fixed obstructive CAD (≥50% reduction in luminal diameter of at least 1 major coronary artery with the extent of luminal diameter reduction determined by trained senior physician observers from films obtained at catheterization) was documented in 49 patients at coronary arteriography, and by a history of documented myocardial infarction in an additional 5 patients. In total, 12 of the 54 patients had documented evidence of previous myocardial infarction at the time of study. Nitrate therapy was stopped at least 6 hours before the studies and propranolol was stopped at least 24 hours before testing. Patients were excluded from the study if valvular or cardiomyopathic abnormalities were apparent by clinical assessment, echocardiography, or cardiac catheterization. All patients were in normal sinus rhythm before and during testing.

In addition, 20 normal subjects aged 23 to 51 years without clinical, echocardiographic, or exercise electrocardiographic evidence of heart disease, and thus with a very low pre-test likelihood of disease, were studied. Normal subjects were volunteers, not patients, from the local community, recruited specifically for study of radionuclide cineangiographic responses and, therefore, were not taking cardioactive medications of any kind.

In each patient or normal subject, radionuclide cineangiography was performed at rest, during exercise, and during cold stimulation using the standard electrocardiogram-gated equilibrium technique previously described in our laboratories.[1,2] During rest and during cold stimulation, studies were acquired in both the 35° right anterior oblique and modified left anterior oblique (15° caudad angulation, visually determined right and left ventricular separation) positions. In 24 patients, right anterior oblique views were not obtained during cold stimulation because of patient refusal to undergo a second cold stress. During exercise, studies were acquired only in the modified left anterior oblique position. In vivo red cell labeling was performed as previously described, using standard methods.[16]

Studies were performed at rest before studies during either stress. After the initial stress study, a 20-minute recovery period was permitted before the second series of studies at rest and during stress was performed. Order of testing was alternated both in normal subjects and in patients with presumed coronary artery abnormalities according to the order of appearance of patients in the laboratory; order of appearance was determined by clerical personnel unaware of the existence or nature of the study.

Exercise stress involved supine bicycle ergometry, beginning at a load of 25 W and increased by 25-W increments every 2 minutes, as previously described.[1,2] Heart rate was monitored every minute and blood pressure every 2 minutes during exercise. Exercise was continued until the development of limiting angina, dyspnea, or fatigue. Imaging was undertaken during maximal exercise, always involving at least the final

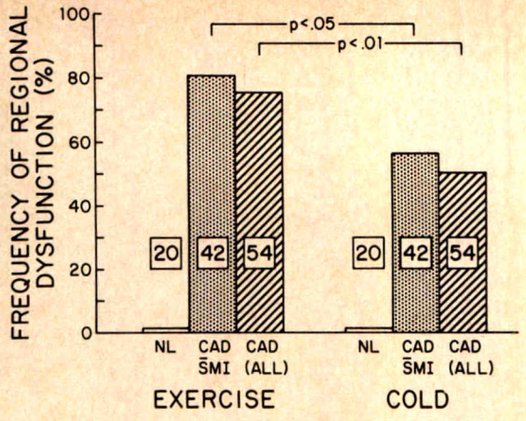

FIGURE 3. Frequency of new regional dysfunction seen with exercise and cold stress during radionuclide cineangiography (RNCA). Numbers in boxes denote population sizes. NL = normal; other abbreviations as in Figure 1.

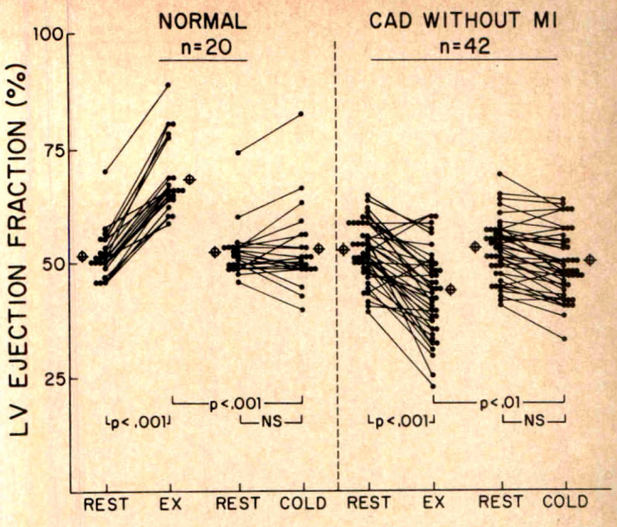

FIGURE 4. Left ventricular ejection fraction response to stress in normal subjects and in patients with coronary artery disease without previous myocardial infarction (MI). CAD = coronary artery disease; EX = exercise; LV = left ventricular.

1.5 minutes of exercise. Cold pressor testing was performed by immersion of the subject's right hand up to the wrist in a bucket of ice water at 4°C. Heart rate was monitored every 30 seconds and blood pressure every minute. After 1 minute of cold exposure, imaging in the left anterior oblique position was undertaken for 2 minutes; the total ice immersion time was 3 minutes. After a 5-minute rest period, the foregoing sequence was repeated with imaging in the right anterior oblique position.

During exercise and in the 3 minutes immediately after exercise, the electrocardiogram was continually monitored with a V_5 lead to monitor anterior vector variations and a modified aVF lead to monitor inferior vector variations. Electrocardiographic recordings were obtained at rest, during maximal exercise, and, if additional abnormalities were noted on the monitoring oscilloscope, during the postexercise period. Electrocardiographic S-T segment variations during exercise were considered indicative of CAD if net S-T segment depression 0.08 seconds after the J point was ≥0.1 mV as compared with the tracing obtained at rest, and the S-T segment slope was 0 or negative.

Radionuclide cineangiograms were assessed visually for evidence of regional dysfunction by observers blinded to the intervention employed and to the clinical and angiographic status of the patient. Studies from normal volunteers and from patients were assessed separately. Regional function assessment is based on the visual recognition of abnormalities in the movement of regional blood volumes.[1–4,9] In this study, a diagnostic regional abnormality was considered present if it was noted in the stress study but was not present in the resting study. Left ventricular ejection fractions were assessed by the count-based method previously described.[17–19] Statistical assessments were performed with the Student's *t* test, analysis of variance, and the chi-square test.

Results

Heart rate and systemic arterial pressure responses to exercise and cold stimulation in each group are depicted in Figures 1 and 2. Heart rate increased significantly ($p < 0.001$) in all groups during exercise, although normal subjects achieved a significantly ($p < 0.001$) higher heart rate than did all other groups. Heart rate tended to increase during cold stimulation in normal subjects; although on the average the heart rate increased to the same degree in patients with CAD, the latter changes achieved statistical significance ($p < 0.01$).

Systemic arterial pressure increased significantly ($p < 0.001$) in all groups during both exercise and cold stimulation. Higher systolic arterial pressures were seen during exercise in normal subjects than in patients with CAD ($p < 0.001$). In contrast, during cold stimulation, patients with CAD had significantly ($p < 0.01$) higher systolic pressure than did normal subjects. However, systolic pressure response was not significantly different in patients with CAD when results during exercise were compared with those obtained during cold stress. The double product (heart rate × systolic arterial pressure) was significantly greater for all subjects during exercise (23,606 ± 7,125) than during cold stimulation (12,841 ± 3,513, $p < 0.001$).

The incidence of regional dysfunction noted during exercise and during cold stimulation is shown in Figure 3. Regional dysfunction was not seen in normal subjects at rest or during either form of stress. Exercise resulted in regional dysfunction in 34 of 42 (81%) patients with fixed obstructive CAD without previous infarction and in 41 of 54 (76%) of all patients with fixed obstructive CAD, significantly higher frequencies of dysfunction than those produced by cold stimulation (57%, $p < 0.05$, in patients without previous infarction, and 50% in all patients, $p < 0.01$). Thus, when regional dysfunction induced during stress is employed as the indicator of CAD, radionuclide cineangiography is more sensitive when exercise, rather than cold stimulation, is employed. The specificity of the test is equivalent (100% in this series) when either form of stress is employed.

Individual responses of left ventricular ejection fraction during exercise are depicted in Figure 4. During exercise, all normal subjects manifested an increase in left ventricular ejection fraction as compared with the

value obtained at rest; the average increase was 18% ($p < 0.001$ compared with the resting value). Among the 42 patients with fixed obstructive CAD without previous infarction, the ejection fraction decreased during exercise in 36 patients (86%). Among all 54 patients with fixed obstructive CAD with and without previous infarction, the ejection fraction decreased during exercise in 44 patients (81%). Of the patients with fixed obstructive CAD who had an increased ejection fraction during exercise, the increase was <5% in 4 patients; previous studies suggest that normal subjects almost invariably have an increase in ejection fraction ≥5% during exercise,[3] a finding corroborated in the normal population in the present study. Using the absence of an increase in ejection fraction of ≥5% from rest to exercise as the criterion for a positive test, the sensitivity of radionuclide cineangiography in detecting patients with CAD was 90% in patients without previous infarction and 91% in all patients with CAD.

Individual ejection fraction responses to cold stimulation are shown in Figure 4. In each patient, the ejection fraction at rest before cold stimulation varied little if at all from the baseline before exercise, and the average ejection fraction for each group was indistinguishable when the 2 resting values were compared. During cold stress, ejection fraction increased in 8 of 20 normal subjects, decreased in 10, and remained unchanged in 2 when compared with resting values. The maximum diminution in ejection fraction was 7%, and only 2 of 20 normal subjects manifested a decrease >5% with cold stress. In patients with CAD without previous infarction, ejection fraction varied widely during cold stimulation, although the average change for the group from rest to cold stress was small (average change −3%, not significant [NS] versus the value at rest). Of the 42 patients without previous infarction, 33 (79%) manifested a decrease during cold stress, but only 11 of 42 (26%) manifested a decrease >5%, the decrement attained by 2 of 20 (10%, NS) normal subjects. Among all 54 patients with CAD, average ejection fraction change during cold stimulation also was small (average change −3%, NS versus value at rest). Forty-two of these 54 (78%) patients manifested a decrease in ejection fraction and in 15 of 54 (28%) the decrease was >5%.

In comparing the efficacy of exercise stress and cold stress in facilitating detection of patients with fixed obstructive CAD from radionuclide cineangiograms, assessment of relative sensitivity and specificity based on changes in ejection fraction is difficult, because of the differences in ejection fraction response of normal subjects to the 2 different stresses. Therefore, to determine which of the 2 stresses permitted the better separation of normal subjects from patients with fixed obstructive CAD when diagnostic criteria were based on ejection fraction changes, the relation between sensitivity and specificity of radionuclide cineangiography for each of a large series of ejection fraction changes was determined for each of the 2 stresses (Fig. 5). As is apparent from Figure 5, over a wide range of ejection fraction changes, sensitivity of radionuclide cineangiography during exercise varied to a moderate extent but throughout this range the test maintained a high specificity. In contrast, during cold stimulation over the same range of ejection fraction changes, when sensitivity was relatively high, specificity was relatively low, and when specificity was high, sensitivity was relatively low. Sensitivity and specificity were equally high when the diagnostic criterion was an ejection fraction change of −1%; at this level, sensitivity and specificity each were 67%, significantly ($p < 0.01$) less than the maximal sensitivity and specificity achievable at a given ejection fraction change with exercise stress (sensitivity 98%, specificity 100% at ejection fraction change of +8%). Thus, over a wide range of stress-induced ejection fraction changes used as the criteria for diagnosis of

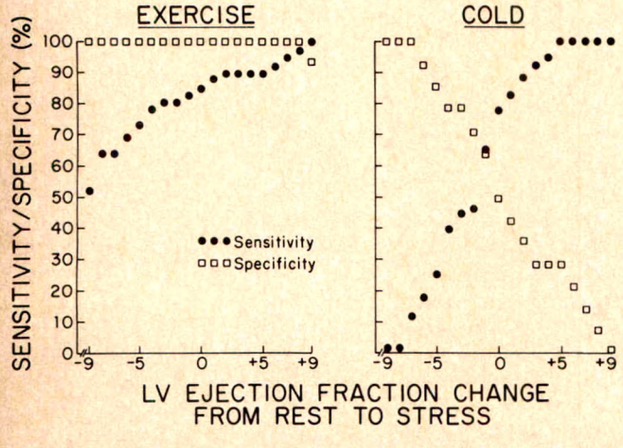

FIGURE 5. Sensitivity and specificity of radionuclide cineangiography in detecting coronary artery disease based on the change in left ventricular ejection fraction from rest to stress in patients with coronary artery disease without previous myocardial infarction. LV = left ventricular.

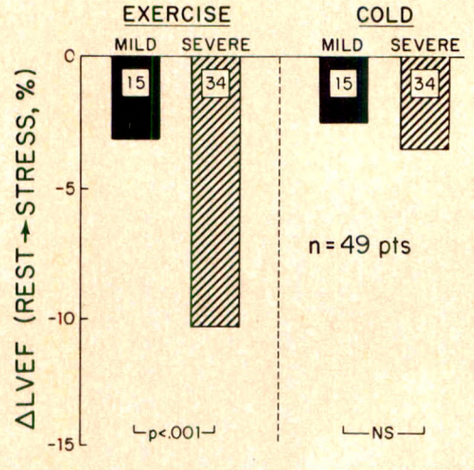

FIGURE 6. Change in left ventricular ejection fraction (ΔLVEF) from rest to stress in relation to anatomic severity of coronary artery disease. MILD = ≥50% luminal diameter obstruction of 1 or 2 major coronary arteries, excluding ≥90% occlusion of proximal left anterior descending coronary artery; SEVERE = ≥50% luminal diameter obstruction of all 3 major coronary arteries or of left main coronary artery, or ≥90% occlusion of proximal left anterior descending coronary artery.

TABLE I Relation of Anatomic and Functional Severity of Coronary Artery Disease

Major Arteries With ≥50% Luminal Diameter Stenosis	n	Mean Ejection Fraction Change From Rest to Stress: Exercise	Cold	p
Single (without proximal LAD)	4	−1.50	−4.75	NS
Double (without proximal LAD)	11	−3.55	−1.55	NS
Triple (without proximal LAD)	13	−8.69	−2.77	<0.02
Proximal LAD (≥90%)	13	−11.31	−3.23	<0.01
Left main	8	−11.38	−4.88	<0.05

* p <0.03.
LAD = left anterior descending; NS = not significant.

fixed obstructive CAD, either sensitivity or specificity, or both, were significantly (p <0.05) lower when cold stress rather than exercise stress was employed.

In comparison with the results of radionuclide cineangiography, sensitivity of exercise electrocardiography (64%; 25 positive results of 39 assessable electrocardiograms) was equivalent to that achieved during cold stimulation (56%, NS) and less than that noted during exercise, although not significantly so (80%, NS), when regional dysfunction was employed as the criterion for the diagnosis of fixed obstructive CAD. Because the presence of exercise electrocardiographic abnormalities was used to exclude subjects from our normal group, no determination of relative specificity could be made and, similarly, no comparison based on ejection fraction criteria could be undertaken.

Comparison between the responses in ejection fraction induced by exercise and by cold indicate that the magnitude of changes produced by exercise generally was more closely related to the severity of anatomic obstructions in the coronary arteries than were changes induced by cold (Fig. 6, Table I). Thus, for example, patients with ≥90% occlusion of the left anterior descending coronary artery proximal to the first septal perforating branch, and patients with triple-vessel or left main coronary artery obstruction, manifested significantly greater diminution in ejection fraction during exercise (average diminution −10%) than did patients with less severe disease (single- or double-vessel occlusions excluding the proximal left anterior descending, average diminution −3%, p <0.001). In contrast, the magnitude of ejection fraction changes during cold stimulation was indistinguishable among patients in the 2 angiographically defined subgroups (NS, Fig. 6, Table I). Moreover, the magnitude of ejection fraction diminution among patients with severe lesions (left main and proximal left anterior descending) was markedly and significantly (p <0.05) greater during exercise than during cold stress, whereas the magnitude of diminution was indistinguishable when the 2 stresses were applied to patients with angiographically less severe obstruction.

Nonetheless, 4 patients with fixed obstructive CAD manifested markedly greater diminution in ejection fraction (difference >5%, the error of the method,[3,20,21] between the 2 stresses) when cold was applied than when exercise was performed (exercise change in ejection fraction 4.3 ± 3.0, cold change in ejection fraction −5.8 ± 3.1, p <0.001). In 1 of these patients with right coronary obstruction alone, regional dysfunction and a 4% decrease in ejection fraction occurred during cold stimulation with no regional dysfunction and a normal increase (8%) in ejection fraction during exercise. These 4 patients could not be distinguished from other patients (in whom exercise caused the greater diminution in ejection fraction) on the basis of absolute or relative heart rate or arterial pressure responses to the 2 stresses.

Discussion

Our data indicate that although cutaneous cold stimulation can produce ischemic changes detectable by radionuclide cineangiography in a majority of patients with fixed obstructive CAD, this form of stress is less effective in producing such changes than is supine bicycle exercise. Thus, the production of regional dysfunction during stress, previously noted to be a highly specific indicator of CAD,[3–10,22] was present in 57% of our patients when cold stimulation was employed, but was present in 81% during bicycle exercise. Moreover, although evidence of global left ventricular dysfunction, indicated by the abnormality of stress-induced change in left ventricular ejection fraction, was present in most patients when either stress was applied, the magnitude of stress-induced changes in normal subjects and in patients with CAD was significantly more easily distinguished when exercise, rather than cold stimulation, was employed. As a result, when the presence of either regional dysfunction or specific changes in ejection fraction was employed as a diagnostic criterion, patients with fixed obstructive CAD were more accurately detected during exercise than during cold stress.

Our results are consistent with the preliminary findings of Wynne et al[23] who evaluated 15 patients with fixed obstructive coronary disease as well as 5 normal subjects. To define the expected response of left ventricular ejection fraction to cold stimulation in normal subjects, systolic blood pressure was increased with methoxamine to levels noted during cold stimulation, and ejection fraction was measured by echocardiography. Applying these methods, Wynne et al[23] determined that ejection fraction could be expected to decrease an average of 4% and a maximum of 10%, with 95% confidence limits. Using this criterion for normal response, Wynne et al[23] found that the sensitivity of radionuclide cineangiography was 33% and the specificity 80% when

cold stimulation was employed. No comparison with results obtained during exercise was performed.

Preliminary results of assessment of 24 patients and 18 normal subjects by Manyari et al[14] indicated sensitivity (38%) similar to those of Wynne et al[23] when cold stimulation was employed with ejection fraction criteria (ejection fraction decrease >6%) for diagnosis. In addition, Manyari et al[14] evaluated the relative response of their patients during exercise and reported results similar to those of the present study (exercise sensitivity 79%) although the specific diagnostic ejection fraction criteria employed were not reported. Neither our results nor those of Wynne or Manyari and their co-workers are quantitatively similar to those of Wainwright et al[13] who found a very pronounced separation of normal subjects and patients with fixed obstructive disease when ejection fraction criteria were applied to the results of radionuclide cineangiography during cold stimulation. Wainwright et al[13] also found radionuclide cineangiography during cold stimulation to be superior to single-lead exercise electrocardiography in detecting patients with fixed obstructive CAD, also inconsistent with our findings. However, Wainwright et al[13] assessed only 12 patients in their comparative study, and the quantitative differences between their results and those of other investigators may have resulted from variations in patient selection within the relatively small study groups in most reports.

Our findings are nonetheless consistent with those of Wainwright et al[13] in that, particularly when we employed regional function determination for purposes of diagnosis, cold stimulation was effective in identifying a significant number of patients with fixed obstructive CAD. These results suggest that cold stimulation may be a useful alternative to exercise testing for this purpose. The mechanisms by which cold stimulation produces myocardial ischemia are not completely understood. Previous investigations indicate that cutaneous application of cold acts through an alpha-adrenergic reflex arc to cause systemic vasoconstriction and thereby to increase total peripheral resistance.[11–13,24,25] The increase in vascular resistance, with the resulting increase in systemic arterial pressure, occurs without the development of reflex bradycardia in most patients and therefore almost invariably increases myocardial oxygen demand. Thus, cold stimulation potentially causes an imbalance between myocardial oxygen supply and demand in patients with fixed obstructive disease. Of note, however, in contrast to the response noted during bicycle exercise, very little increase in heart rate occurs during cold stimulation. Therefore, myocardial oxygen consumption, as indicated by the rate-pressure product, is significantly higher during bicycle exercise than during cold stimulation, perhaps accounting at least in part for the greater accuracy of radionuclide cineangiography in detecting patients with fixed obstructive CAD when exercise is employed.

However, although increases in myocardial oxygen demand may account for the ischemic changes seen during cold stress in patients with fixed obstructive disease, recent reports suggest that cold stimulation also may produce myocardial ischemia by restricting myocardial oxygen supply.[24,25] Thus, Neill et al[12] observed that cold exposure provoked angina and lactate production when the rate-pressure product was significantly lower than that associated with angina during atrial pacing. Consistent with these findings and using direct measurements of coronary vascular resistance, Mudge et al[11] documented an increase both in systemic and coronary resistance in patients with fixed obstructive CAD during cold stimulation, with a concomitant reduction in coronary flow in 3 patients and with the development of angina in 4 of 12 patients; conversely, during atrial pacing to ischemia and angina, coronary resistance decreased and coronary blood flow increased.[25] Normal subjects, despite systemic arterial vasopressor responses similar to those in patients, all had decreased coronary vascular resistance during cold stimulation.[11]

Although the site of cold-mediated vasoconstriction theoretically might be the arteriolar or large arterial level, or both, Raizner et al[15] recently demonstrated cold-induced focal coronary artery spasm during arteriography in 7 of 35 patients with fixed obstructive lesions. Two of the 7 patients with spasm had chronic typical angina pectoris, indicating that at least in some patients with fixed obstructive disease, cold-induced ischemia may result in part from dynamic obstruction at the level of the large coronary arteries. Although this phenomenon is rare, it also appears to occur occasionally during exercise.[26] These results also suggest that a spectrum of coronary vascular reactivity to cold stimulation exists, and that this form of stress may be of particular utility in efforts to detect patients with a dynamic component of coronary artery obstruction. Of note in this regard are the preliminary data of Perez-Balino et al[27] who found regional abnormalities in 7 of 10 patients with documented spasm during cold stimulation when radionuclide cineangiography was performed. These findings suggest that radionuclide cineangiography may be of particular value in the noninvasive detection of patients with dynamic coronary artery obstruction during cold stimulation. Such a possibility is of potential clinical importance, because the current availability of calcium slow channel blocking agents may provide a therapy particularly well suited to patients whose ischemic disease is mediated in part by dynamic obstruction.[28–33] Further studies will be necessary to determine the clinical importance of these speculations.

Ischemia-Associated Intraventricular Conduction Disturbances During Exercise Testing as a Predictor of Proximal Left Anterior Descending Coronary Artery Disease

KEVIN J. BORAN, MD, RENE A. OLIVEROS, MD, CHARLES A. BOUCHER, MD, CHARLES H. BECKMANN, MD, and JOHN F. SEAWORTH, MD

To determine the incidence and significance of transient intraventricular conduction abnormalities occurring in association with myocardial ischemia during exercise testing, the recordings of 2,200 consecutive exercise tests were reviewed. Ten patients (0.45%) were identified as having both ischemia and intraventricular conduction abnormalities that developed transiently during the exercise test. In all 10 patients both typical angina and electrocardiographic evidence of ischemia developed during exercise. Among the 10 patients, left anterior hemiblock developed in 4, left posterior hemiblock in 2, right bundle branch block (RBBB) in 2, RBBB with left axis deviation in 1, and left anterior hemiblock progressing to complete left bundle branch block (LBBB) in 1. All 10 patients had cardiac catheterization showing significant obstruction of the left anterior descending (LAD) coronary artery at or before the origin of the first septal branch. Eight patients were treated surgically and 2 medically, all with relief of ischemic symptoms. Nine of the 10 had repeat exercise stress testing without angina or electrocardiographic evidence of ischemia and without recurrence of the transient intraventricular conduction disturbance.

It is concluded that the development of transient intraventricular conduction abnormalities associated with myocardial ischemia during exercise testing is an uncommon occurrence (0.45%). When such conduction disturbances do develop, the existence of significant disease in the proximal portion of the LAD coronary artery is strongly suggested. With control of myocardial ischemia, the transient conduction disturbances during exercise are ameliorated.

Exercise electrocardiography is widely used in evaluating patients with coronary artery disease. Although the significance of S-T segment changes is widely appreciated, less common abnormalities such as transient conduction defects may also occur. However, the incidence of transient intraventricular conduction abnormalities during exercise and their correlation with angiographic data have not been clarified.[1–5] We previously reported 2 cases of intermittent left anterior hemiblock during exercise-induced ischemia.[6] Both patients had significant obstruction of the proximal left anterior descending (LAD) coronary artery before or involving the origin of the first septal perforator branch. To put this observation in perspective, we reviewed a consecutive exercise test experience of 2,200 patients and analyzed the records of the 10 patients in the group, including the 2 previously reported on, in whom transient intraventricular conduction abnormalities developed in association with myocardial ischemia during exercise. The incidence and clinical significance of this finding are presented.

Methods

Patient population: The electrocardiographic (ECG) records of the exercise stress tests that were performed on 2,200 consecutive patients over a 3-year period were reviewed. These represented all exercise tests performed at a large referral hospital and included tests performed to evaluate the presence and severity of coronary artery disease as well as the functional capacity of patients with cardiac disease. Ten patients (0.45%) had transient intraventricular conduction defects and evidence of myocardial ischemia. All 10 patients had both ECG evidence of myocardial ischemia and typical exertional angina. There were 8 male and 2 female patients aged 37 to 71 years (mean 51). Coronary artery bypass graft surgery was performed in 8, of whom 7 underwent repeat exercise testing within 1 to 3 months. Two patients were managed with medical therapy and both underwent repeat exercise testing within 3 months. There were 4 patients in the total group of

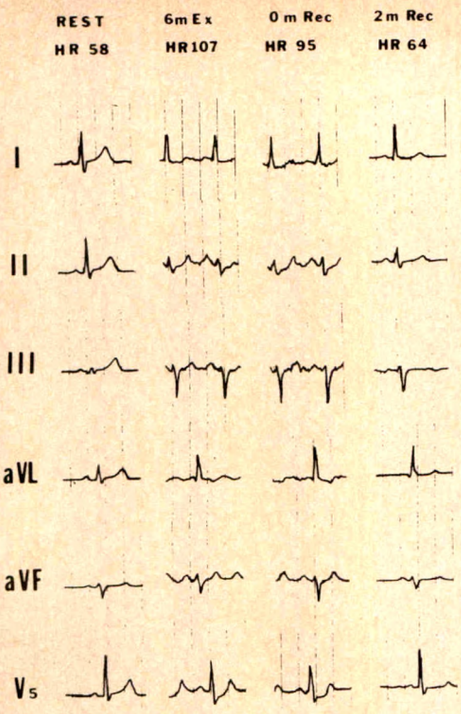

FIGURE 1. Twelve-lead electrocardiogram of a patient in whom left anterior fascicular block developed at the sixth minute of exercise. The conduction disturbance disappeared by the second minute of recovery. Ex = exercise; HR = heart rate; Rec = recovery.

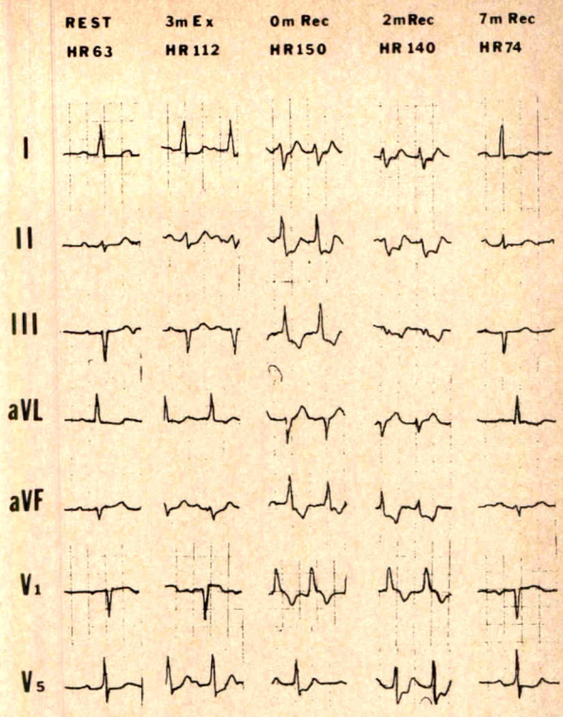

FIGURE 2. Twelve-lead electrocardiogram of patient 5 in whom left posterior fascicular block developed after 6 minutes of exercise. The electrocardiogram has returned to control after the seventh minute of recovery. Ex = exercise; HR = heart rate; Rec = recovery.

2,200 in whom rate-related conduction disturbances developed. In 3 of these patients left anterior hemiblock developed and in 1, left bundle branch block developed. None of the 4 had either angina or S-T changes suggesting myocardial ischemia. None was diagnosed as having coronary artery disease. These patients received no therapy and on repeat exercise testing they had reproducible rate-related intraventricular conduction disturbances. They were not included in the study population because of the intention of defining the significance of those transient intraventricular conduction disturbances that were associated with myocardial ischemia.

Exercise protocol: Nine patients had exercise testing using the Bruce multistage treadmill protocol,[7] and 1 patient was exercised using the United States Air Force School of Aviation Medicine protocol.[8] Before the test, blood pressure and heart rate were taken with the patient in the supine and upright position. During exercise, continuous ECG monitoring was performed using 3 leads. Blood pressure, heart rate, and 12-lead electrocardiogram were obtained at 1-minute intervals throughout exercise and for 5 minutes after exercise. The patients exercised to a symptom-limited endpoint such as severe angina pectoris, fatigue, shortness of breath, hypotension, or severe ventricular dysrhythmia.

An ischemic ECG response was defined as 1.0 mm of horizontal or downsloping S-T segment depression that persisted for at least 0.08 second.[9,10] The mean QRS axis in the frontal plane was determined using the method described by Laiken et al[11] in which the QRS axis is obtained from any 1 of 3 different lead combinations using a single, compact table. The time of occurrence and the duration of the conduction disturbances were noted as was the intraventricular conduction time.

The fascicular blocks were diagnosed using the criteria prepared by the Criteria Committee of the New York Heart Association.[12] Left anterior hemiblock is diagnosed in the presence of marked left axis deviation (−45° to −90°) and an increase of no more than 0.02 second over the original QRS duration. In addition, there must be a q in leads I and aVL and an rS in leads II, III, and aVF. Left posterior hemiblock is diagnosed in the presence of right axis deviation (+90° to 100°), minimal change in QRS duration which is 0.09 to 0.10 second, and a qR in leads II, III, and aVF. This diagnosis was made after exclusion of right ventricular enlargement, emphysema, and extensive lateral wall myocardial infarction by physical examination, 12-lead electrocardiogram, and chest X-ray.

Catheterization protocol: All patients underwent cardiac catheterization within 1 to 2 weeks after the initial treadmill test. Left heart catheterization was performed through the percutaneous femoral approach. Left ventricular cineangiograms and selective coronary arteriograms were recorded on 35 mm film at 60 frames/s using a cesium iodide image-intensifier system. Coronary arterial stenosis was estimated as a percentage decrease in luminal diameter. Stenosis >70% was considered hemodynamically significant. Left ventricular volumes and ejection fraction were calculated from the right anterior oblique ventriculogram using the area-length method.[13]

Statistical analysis: The results of the exercise test were expressed as the mean ± standard deviation. The results before and after exercise were compared using a paired t test.

Results

Ten of 2,200 patients (0.45%) undergoing an exercise tolerance test had intermittent intraventricular conduction disorders in association with myocardial ischemia. These included left anterior hemiblock in 4 patients (Fig. 1), left posterior hemiblock in 2 (Fig. 2),

TABLE I Clinical Data

Pt	IVCD	Age (yr) & Sex	Previous MI	Angina	Medication
1	LAH	59M	0	+	IDN, NTG, P
2	LAH	37M	0	+	0
3	LAH	51M	0	+	IDN, P
4	LAH	50M	0	+	0
5	LPH	71M	+	+	IDN, P

7	RBBB	52M	0	+	0
8	RBBB	41F	0	+	0
9	RBBB/LAD	52M	0	+	0
10	LAH/LBBB	40M	0	+	IDN, NTG

IDN = isorbide dinitrate; IVCD = intraventricular conduction defects; LAD = left axis deviation; LAH = left anterior hemiblock; LPH = left posterior hemiblock; LBBB = left bundle branch block; MI = myocardial infarct; NTG = nitroglycerin; P = propranolol; Pt = patient; RBBB = right bundle branch block; 0 = no; + = yes.

right bundle branch block (RBBB) in 2, RBBB with left axis deviation in 1, and left anterior hemiblock progressing to complete left bundle branch block (LBBB) in 1. The clinical data in these patients are shown in Table I. As shown in this table, no patient was receiving any drug known to prolong the QRS duration. The individual and mean exercise test results are shown in Table II. The results shown in this table for the exercise electrocardiogram represent the heart rate, QRS axis, and QRS duration at the time of onset of the conduction disturbance. In Patients 1 through 9, these data represent the initial and sole conduction disturbance. In Patient 10 the values are those that existed at the time of development of complete LBBB. In all patients angina and ECG evidence of ischemia developed during exercise and in all 10 patients the chest pain and S-T changes occurred before the development of the intraventricular conduction disturbance. A hemiblock alone developed in 6 patients, and in 4 patients complete bundle branch block developed. The mean QRS was 0.085 at rest and increased during exercise to 0.110 second ($p < 0.01$). The onset of the intraventricular conduction defect occurred after an average of 5.6 minutes of exercise (range 3 to 12) and the conduction defect persisted an average of 3.1 minutes (range 1.5 to 9). In all 10 patients the conduction defect persisted for the remainder of exercise and disappeared only during the recovery period. Table II shows the exercise time at the onset of the conduction defect as well as the time of duration of the conduction defect in each patient.

Catheterization data: Left ventriculography and coronary arteriography data are shown in Table III. The left ventricular ejection fraction was reduced (<0.50) in 3 patients, but the mean value for the group was 0.56 ± 0.08 which is within the normal range of 0.64 ± 0.07 previously reported from our laboratory.[14] All 3 patients with a low ejection fraction and 4 of 7 patients with a normal ejection fraction had regional wall motion abnormalities, particularly in the anterior and apical segments. All 10 patients had significant obstruction of the LAD coronary artery before or at the origin of the first septal branch (Fig. 3). Three patients had single-vessel disease, 3 had double-vessel involvement, and 4 had triple-vessel disease. Two patients had stenosis of the left main coronary artery and these 2 patients had left posterior hemiblock during exercise. Three patients had collateral circulation whereas in the other 7, collateral circulation was absent.

Follow-up evaluation: Nine of the 10 patients were reevaluated by exercise testing within 3 months of coronary bypass surgery or the institution of medical therapy. All demonstrated improvement in terms of a longer duration of exercise and a higher attainable maximal heart rate. The resting mean heart rate was 75 ± 8 beats/min and increased to 142 ± 22 beats/min with exercise ($p < 0.001$). No patient developed a significant axis shift with exercise with the mean QRS axis at rest being +70° and during exercise +77° (p not significant [NS]). In no patient did intraventricular conduction abnormalities develop during exercise. All patients exercised without developing angina or S-T segment abnormalities.

Discussion

Exercise-induced intraventricular conduction defects in association with myocardial ischemia were an uncommon finding in our laboratory (0.45% of cases) and represented a spectrum of defects. The most common was left anterior hemiblock. Rosenbaum et al[15] reported the first 5 cases of intermittent left anterior hemiblock. In 2 of their cases the cause was coronary artery disease, particularly LAD disease, and this association has been confirmed by several investigators.[1–5,6,16] All 4 of our patients with left anterior hemiblock had significant

ECG = electrocardiogram; HR = heart rate. Other abbreviations as in Table I.

obstruction of the LAD artery proximal to or at the origin of the first septal branch. In all 4 patients the conduction defect was accompanied by ECG manifestations of myocardial ischemia, and the conduction disturbance resolved when the ischemia subsided.

Left posterior hemiblock was a less common transient abnormality in our study. Hegge et al[1] reported right axis deviation during exercise in 9 patients, but only 3 of them fulfilled the ECG criteria for left posterior hemiblock. One of their patients had significant disease of the left main coronary artery and 2 had significant obstruction of the LAD and right coronary arteries. Bobba et al[5] reported on 4 patients with transient left posterior hemiblock during exercise. All of them had significant disease of the proximal right coronary artery and 2 had significant disease of the left coronary artery.

Exercise-induced complete bundle branch block occurred in 4 of our patients during exercise. All of them had significant proximal obstruction in the LAD coronary artery. We had 2 patients with transient RBBB. Whinnery et al[17] reported on a patient who had intermittent RBBB during exercise. However, that patient had no history of angina pectoris. The conduction abnormality was not associated with S-T abnormalities and persisted throughout the recovery period. At cardiac catheterization he had a normal LAD artery but 60% obstruction of the left circumflex coronary artery. Also, this patient was found to have persistent RBBB on subsequent Holter monitoring. The 2 patients with RBBB in the present study did have both angina and ECG evidence of ischemia during the exercise test and both had only transient occurrence of the conduction abnormality that resolved when the other signs of myocardial ischemia resolved. In 1 patient in the present study, transient left anterior hemiblock developed followed by complete LBBB during exercise. This association occurring in an acute setting has not previously been reported.

Transient bundle branch block during exercise is strongly related to reversible ischemia. This finding is in contrast to chronic RBBB[17,18] or LBBB[19] which may be an isolated conduction system abnormality. The response to bypass surgery with relief of ischemia and subsequent disappearance of the conduction abnormality confirms this observation. Very significantly, all 10 patients in this study in whom transient intraventricular conduction disturbances developed proved to have significant narrowing of the proximal portion of the LAD coronary artery. In 3 patients this was the only coronary lesion, whereas in 7 other patients coexistent lesions of other coronary arteries were present. Many clinicians attach a high degree of importance to lesions of the LAD artery proximal to the first septal perforator. In many centers such lesions are bypassed even if they are the sole lesion or the patient has only 2-vessel coronary artery disease. The justification given for this surgical approach is based on the large amount of myocardium, including the conduction system, that is placed at jeopardy by such lesions. The results of the present study indicate that the occurrence of intra-

ventricular conduction disturbances associated with myocardial ischemia during exercise testing is strongly suggestive of the presence of significant disease in the proximal portion of the LAD coronary artery.

Acknowledgment: It is a pleasure to acknowledge the encouragement received during the performance of this study from many colleagues. We are particularly grateful to Drs. Frederick Weiland, Robert Chilton, Paul Dlabal, Victor Froelicher, Michael Gordon, Gerald Koppes, William Kruyer, Gordon Haycraft, Robert Slama, B. Shields Stutts, and Gregory Uhl. The secretarial assistance of Carmen P. Varela is greatly appreciated.

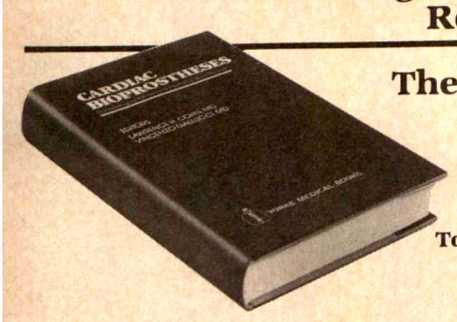
Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982



The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.

To order your copy of this important new book use the order form below.

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

Table of Contents

Section 1 CLINICAL ANALYSIS 1. The Evolution of the Biological Valve **2.** Heart Valve Replacement with the Hancock Bioprosthesis: A 5-11 Year Follow-up **3.** A 14-Year Experience with Valvular Bioprostheses: Valve Survival and Patient Survival **4.** A Thousand Porcine Bioprostheses Revisited. Do They Conform with the Expected Pattern? **5.** Clinical Durability of the Pericardial Xenograft Valve: 11 Years' Experience **6.** Long-term Results of 159 Porcine Valve Implantations **7.** Mid- and Long-term Evaluation of Porcine Bioprosthetic Valves: A 6-Year Experience

Section 2 HEMODYNAMICS 8. Hemodynamic Evaluation of the Hancock Bioprosthesis in the Mitral Position: A 1-7 Year Follow-up **9.** Hemodynamic Evaluation of the Carpentier-Edwards Standard and Improved Anulus Bioprostheses **10.** Hemodynamic Evaluation in Valvular Patients Carrying Low Profile Bioprostheses **11.** Noninvasive Scintigraphic Assessment of Left and Right Ventricular Function in Patients with Bioprosthetic Mitral Valves at Long-term Risk **12.** Orifice View Roentgenography for Evaluation of the Orifice Area of Bioprosthetic Valves

Section 3 THROMBOEMBOLISM 13. Alterations in Valvular Surgery: Biological Valves **14.** Early and Late Results of Porcine Bioprostheses Versus Mechanical Prostheses in Aortic and Mitral Positions **15.** Mitral Bioprostheses in 202 Patients with Chronic Atrial Fibrillation, Giant Left Atrium, and Atrial Thrombi: Long-term Results with No Anticoagulation **16.** Thromboembolism and Anticoagulation after Isolated Mitral Valve Replacement with Porcine Heterografts **17.** Preoperative Determinants of Return to Sinus Rhythm after Valve Replacement **18.** Porcine Bioprostheses Versus Mechanical Valvular Substitutes: A Retrospective Comparative Analysis

Section 4 PEDIATRIC VALVE REPLACEMENT 19. Valved Conduits: A Panacea for Complex Congenital Heart Defects? **20.** Factors Influencing Late Results of Extracardiac Conduit Repair for Congenital Cardiac Defects **21.** Calcification of Porcine Bioprostheses in Children **22.** Valve Replacement in Children: Biological Versus Mechanical Valves **23.** Bioprosthetic Valve Replacement in Children **24.** Aortic Root Replacement **25.** Conduits Containing Antibiotic Preserved Homografts in the Treatment Of Complex Congenital Heart Defects **26.** Dura Mater Bioprosthesis in Young Patients

Section 5 EXPERIMENTAL PATHOLOGY 27. Experimental Evaluation of Bioprosthetic Valves Implanted in Sheep **28.** Role of Mechanical Stress in Calcification of Bioprostheses **29.** Inhibition of Mineralization of Glutaraldehyde-fixed Hancock Bioprosthetic Heart Valves **30.** Prevention of Tissue Valve Calcification by Chemical Techniques

Section 6 EXPLANT PATHOLOGY 31. Complications of Replacement of either the Mitral or Aortic Valve or Both by either Mechanical or Bioprosthetic Valves **32.** Pathogenesis and Stages of Bioprosthetic Infection **33.** Structure and Classification of Cuspal Tears and Perforations in Porcine Bioprosthetic Cardiac Valves Implanted in Patients **34.** Pathological Substrates of Porcine Valve Dysfunction **35.** Mode of Failure in 226 Explanted Biological and Bioprosthetic Valves

Transderm®-Nitro
nitroglycerin
Nitroglycerin—for more than 100 years the classic therapy for angina—now becomes more convenient, more simple, more practical.

First-step anginal prophylaxis

Transderm®-Nitro

nitroglycerin

A step ahead of long-acting oral nitrates

"Transdermal delivery of nitroglycerin . . . overcomes the inherent problems of the oral dosage forms regarding . . . bioavailability, convenience and compliance."*

24-hour sustained therapeutic blood levels of nitroglycerin.
In contrast, so-called long-acting oral nitrates must be given in repeated doses throughout the day.

Eliminates the first-pass effect.
Unlike oral nitrates, which are predominantly inactivated in the liver, transdermal nitroglycerin bypasses the liver and enters directly into systemic circulation.

Only one simple application a day.
Avoids the inconvenience of multiple dosages.

Small, cosmetically acceptable and well tolerated.
Will not leak or stain clothing. May even be worn while bathing or swimming. Few reports of skin irritation.

Note: Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

*Black CD: Transdermal drug delivery systems. *US Pharmacist* 1982 (Nov); 7(11):49-78.

C I B A

Transderm®-Nitro

(nitroglycerin)
Transdermal Therapeutic System

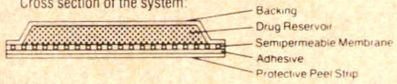
DESCRIPTION

Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semi-permeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers as shown below. Proceeding from the visible surface towards the surface attached to the skin these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, colloidal silicon dioxide, and silicone medical fluid; 3) an ethylene vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

Cross section of the system:



ACTIONS

When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE

Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS

Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS

In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS

Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS

Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION

Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS

A patient leaflet is supplied with the systems.

The best images
and a unique
technology...

The new PASS™ echocardiography system from General Electric expands the advantages of phased array ultrasound...and delivers a difference in M-mode and 2D images beyond your expectations.

More accurate clinical information, faster

Only GE applies baseband signal processing to phased array echocardiography and couples it with superior transducer design. Your clinical studies reap the benefits of this exclusive combination.

Specifically, baseband processing, with its greater signal timing accuracy, significantly improves image resolution and penetration. And baseband processing eliminates artifacts and other types of electronic noise. A continuous focusing ability provides a focused view of the heart from the near field to the deepest penetration; an important improvement over the zone focusing of other systems. As a result, you can image structures as fine as 1 mm; see better edge definition; and can differentiate soft tissue more precisely. Also, advanced phased array display capability permits time-efficient simultaneous viewing of M-mode and 2D images. Two M-mode images or two 2D images allow accurate quantification and diagnostic flexibility.

Image a wider range of patients with more transducer options

From premature neonate to obese adult, the PASS system widens the range of scannable patients. For neonatal and pediatric studies, the PASS system offers the first clinically proven 5 MHz phased array image without near field noise. Average size adults can be imaged at 3.3 MHz for optimal resolution. Obese adults can be imaged at 2.5 MHz for maximum penetration. And because PASS is a phased array system, its small, lightweight transducers offer better acoustic access compared to mechanical sector systems.

More options for future capability

Best of all, you can build on today's PASS system capability for tomorrow's imaging requirements. Because upgradeability is designed-in, you'll soon be able to add doppler; plus other technological advances as they are developed. In addition, self-diagnostic features facilitate servicing and help keep the system on the job.

See the difference the PASS system can make in your clinical studies. Contact your GE representative.

...clinical studies you can trust.

We bring good things to life.

GENERAL ELECTRIC

A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

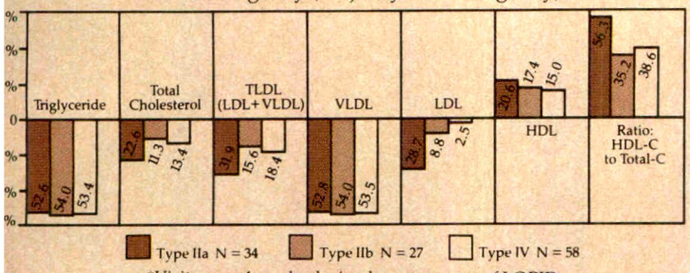
LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

Artist's interpretation of VLDL in bloodstream

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.
†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

LOPID®
(gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

PD-56-JA-1333-P-1 (11-82)

Determinants of the Incidence and Severity of Ventricular Arrhythmias in Aortic Valve Disease

KLAUS v. OLSHAUSEN, MD, FRANZ SCHWARZ, MD, JÖRG APFELBACH, NORBERT RÖHRIG, MD, BURKHARDT KRÄMER, MD, and WOLFGANG KÜBLER, MD,
With the technical assistance of SONJA GUND

The incidence of ventricular arrhythmias in patients with aortic valve disease was investigated. Twenty-four-hour ambulatory electrocardiographic recordings were obtained in 93 patients without coronary artery disease (aortic stenosis [AS], n = 38; combined AS and aortic regurgitation [AR], n = 27; and AR only, n = 28). The arrhythmias were compared with the hemodynamic findings of cardiac catheterization. Ventricular premature beats (VPB) were noted in 78 patients (84%). They were rare (<100 VPB/22 hours) in 40 patients (43%), moderately frequent (101 to 1,000 VPB/22 hours) in 23 patients (25%), and frequent (>1,000 VPB/22 hours) in 15 patients (16%). Multiformity was found in 47 (51%), paired VPB in 32 (34%), and ventricular tachycardia in 17 (18%) of the 93 patients studied. The occurrence of ventricular arrhythmia was not related to the type of valve lesion, to the transvalvular gradient in patients with AS, or to the degree of regurgitation in patients with AR. In contrast, the grade of arrhythmia showed a negative correlation with left ventricular ejection fraction (AS, $r_s = -0.58$; AS and AR, $r_s = -0.67$; AR, $r_s = -0.78$; all $p < 0.001$) and a positive correlation with peak systolic left ventricular wall stress (AS, $r_s = 0.56$; AS and AR, $r_s = 0.56$; AR, $r_s = 0.57$; all $p < 0.001$). The frequency of VPB also showed a negative correlation with left ventricular ejection fraction (AS, $r_s = -0.63$; AS and AR, $r_s = -0.65$; AR, $r_s = -0.71$; all $p < 0.001$).

This study indicates that ventricular arrhythmias are present in a large number of patients with aortic valve disease. The severity of arrhythmias is strongly influenced by myocardial performance. Thus, severe arrhythmias are frequently a sign of impaired left ventricular function.

Sudden cardiac death is a well-known complication in patients with aortic stenosis (AS).[1] Although malignant ventricular tachyarrhythmias are proposed as a cause of these lethal outcomes,[2] there is little detailed information about the incidence and severity of ventricular arrhythmias in patients with AS or aortic regurgitation (AR). This study investigates the incidence and severity of ventricular arrhythmias in 93 patients with isolated aortic valve disease (without coronary artery disease) by 24-hour ambulatory electrocardiographic monitoring. These findings were related to hemodynamic data as assessed by cardiac catheterization to analyze the factors influencing the occurrence of ventricular arrhythmias in aortic valve disease.

From the Medizinische Universitätsklinik, Abteilung Innere Medizin III (Kardiologie), Heidelberg, West Germany. This study was supported in part by the Deutsche Forschungsgemeinschaft (Bad Godesberg) within the SFB 90- Kardiovaskuläres System, University of Heidelberg. Manuscript received August 31, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

Address for reprints: Klaus v. Olshausen, MD, Innere Medizin III, Bergheimer Strasse 58, D-6900 Heidelberg, West Germany.

Methods

Patients: All 93 patients with aortic valve disease were studied between July 1980 and July 1982. Seventy-six were men and 17 were women; their ages ranged from 18 to 70 years (mean 50 ± 13). A patient was included in the study if the following criteria were fulfilled: (1) presence of isolated aortic valve disease, without previous surgical treatment; (2) absence of coronary heart disease (proven by selective coronary angiography); that is, patients with ≥25% luminal narrowing of a major coronary vessel were excluded; (3) normal serum potassium level (3.5 to 5.0 mEq/liter) on the day of ambulatory monitoring (±24 hours); and (4) absence of specific antiarrhythmic therapy.

Cardiac catheterization: All 93 patients were studied by right- and left-sided cardiac catheterization including coro-

Grade = highest grade of ventricular arrhythmia; VPB = ventricular premature beat; VT = ventricular tachycardia.

nary angiography. An 8.5F Brockenbrough catheter was positioned by transseptal puncture into the left ventricle and a pigtail catheter (7F) was positioned retrogradely into the aortic root. Pressures were recorded before injection of contrast medium. Single-plane 35 mm cineangiograms of the left ventricle were filmed (50 ml Urografin® 76, 50 frames/s, 30° right anterior oblique projection, Philips image intensifier system). Left ventricular volumes and left ventricular ejection fraction were calculated using the computer-aided area-length method (system Mennen-Greatbatch).

The orifice area of the aortic valve in patients with pure AS was calculated using the formula of Gorlin et al.[3] It was normalized to body surface area. The severity of AR was assessed by aortic root angiography.[4] The cardiac index was determined by the Fick principle. Peak systolic left ventricular wall stress was calculated according to the method of Gaasch et al.[5]

Patients with a calculated valve area ≤ 0.6 cm^2/m^2 and AR of less than grade 2+ of 4+ grades were classified as having AS. Patients with a regurgitation of grade $\geq 2+$ and a transvalvular gradient <25 mm Hg were classified as having predominant AR. Patients who did not meet these criteria were classified as having combined AS and AR.

Ambulatory electrocardiographic monitoring: Within 48 hours before or after cardiac catheterization, an ambulatory electrocardiographic monitoring with a mean duration of 22 hours (range 18 to 25) was performed. The ambulatory electrocardiogram was recorded on a 1-channel Oxford Medilog Mark I recorder using a bipolar V_1 to V_5 lead system. The recordings were analyzed semiautomatically using the Reynolds Pathfinder system and a Digital PDP 11/03 computer with 2 floppy discs. During automatic analysis all tapes were simultaneously scanned visually on the oscilloscope by an experienced technician. When arrhythmia was suspected, that portion of the tape was printed out. Examples of all types of ventricular premature beats (VPB), couplets, and ventricular tachycardia were printed on paper and interpreted by a cardiologist.

The accuracy of the Medilog-Pathfinder system in detecting VPB and repetitive arrhythmias was validated recently.[6–8] In a study of 31 1-hour electrocardiographic recording segments, system output was compared with a beat-by-beat hand count of the electrocardiogram. These segments contained 139,583 normal beats and 9,146 VPB. The predictive value was 97% for VPB and 92% for paired VPB and ventricular tachycardia. The sensitivity was 95% and 92%, respectively. The false-positive rate was 2.7% for VPB.[6]

A modified Lown grading system as described by Ryan et al[9] for ventricular arrhythmias was used: grade 0, no VPB in 22 hours; grade 1, occasional VPB but ≤30 in any hour of monitoring; grade 2, >30 VPB in any hour of monitoring; grade 3, multiform VPB; grade 4A, couplets (2 consecutive VPB); grade 4B, ventricular tachycardia (≥3 VPB in succession with a frequency >100/min).

Statistical analysis: Data are expressed as mean values ± standard deviation. The correlations between ventricular arrhythmias (incidence of VPB, grade of ventricular arrhythmia) and clinical and hemodynamic data were performed by calculating the rank correlation coefficient r_s of Spearman.[10] If more than 20% ties occurred, the modification of Kendall was applied.[10] With 2-tailed testing, a probability value <0.05 was considered significant.

For calculation purposes, the grade 4A of ventricular arrhythmia was assigned the value 4.0 and the grade 4B the value 4.5. All other grades were assigned their related numbers. Three or more mean values of ranks were compared by means of the H-test by Kruskal and Wallis.[10] Mean values of hemodynamic variables were compared by means of the t test for unpaired data.[10]

Results

Clinical and hemodynamic data: The functional class of the patient was determined according to the New York Heart Association classification.[11] Thus, 2 patients were determined to be in class I, 14 in class II, 62 in a class III, and 15 in class IV. Thirty-eight patients had AS, 27 patients had AS and AR, and 28 patients had AR. The mean functional class yielded no significant difference between the 3 groups (AS, 2.9 ± 0.7; AS and AR, 3.1 ± 0.6; and AR, 3.0 ± 0.6). The mean age of the patients with AS was 53 ± 14 years, of the patients with AS and AR, 49 ± 11 years, and of the patients with AR, 47 ± 11 years. These differences in age were insignificant.

The mean transvalvular aortic gradient was 94 ± 37 mm Hg in patients with AS, and 85 ± 33 mm Hg in patients with AS and AR. The mean aortic valve area normalized to body surface area was 0.28 ± 17 cm^2/m^2 in patients with AS. The mean degree of regurgitation was 2.9 ± 0.8 in patients with AS and AR and 3.4 ± 0.6 in patients with AR. The mean left ventricular ejection fraction was 66 ± 16% in patients with AS, 54 ± 18% in

AR = aortic regurgitation; AS = aortic stenosis.

patients with AS and AR, and 60 ± 13% in patients with AR.

The electrocardiogram at rest revealed sinus rhythm in all patients except 2 with AS who had atrial fibrillation. Five patients had left bundle branch block (3 with AS, 2 with AS and AR). Two patients had right bundle branch block (1 with AS and AR, 1 with AR).

Reproducibility of ambulatory electrocardiographic monitoring (Table I): To assess spontaneous variability in arrhythmia frequency in patients with aortic valve disease, we evaluated two 24-hour ambulatory electrocardiographic recordings registered within 1 week in 12 patients. For the study, the results of the first recording were taken. Comparison of the 2 recordings revealed that the mean VPB frequency/22 hours decreased from 1,192 to 825, due mainly to a marked reduction in VPB in Patient 9, who had ventricular bigeminy in the first recording. The mean value of the highest grade of arrhythmia decreased from 3.1 to 2.8 (difference not significant [NS]); only 3 patients remained in the same grade (Patients 3, 9, and 12). It is noteworthy that only 1 patient (Patient 4) had a change in grade from no or unifocal VPB (grades 0 to 2) to complex VPB (grades 3 to 4B), or vice versa. Thus, although 75% of these 12 patients had a change in their highest grade of arrhythmia, 92% remained in their group of no or unifocal (grades 0 to 2) or complex VPB (grades 3 to 4B).

Incidence of VPB (Table II): Fifteen patients (16%) had no ventricular arrhythmia noted during the recording period. In the remaining 78 patients (84%), VPB frequency ranged from 1 to 7,510 VPB/22 hours, with a mean value of 790 ± 1,588. Ventricular premature beats were rare (<100 VPB/22 hours) in 40 patients (43%), moderately frequent (101 to 1,000 VPB/22 hours) in 23 patients (25%), and frequent (>1,000 VPB/22 hours) in 15 patients (16%).

Incidence of VPB and left ventricular performance (Fig. 1): A highly significant inverse correlation was found between the left ventricular ejection fraction and the VPB frequency in all 3 study groups (AS, $r_s = -0.63$; AS and AR, $r_s = -0.65$; AR, $r_s = -0.71$; all $p < 0.001$) (Fig. 1). Other clinical and hemodynamic variables such as New York Heart Association func-

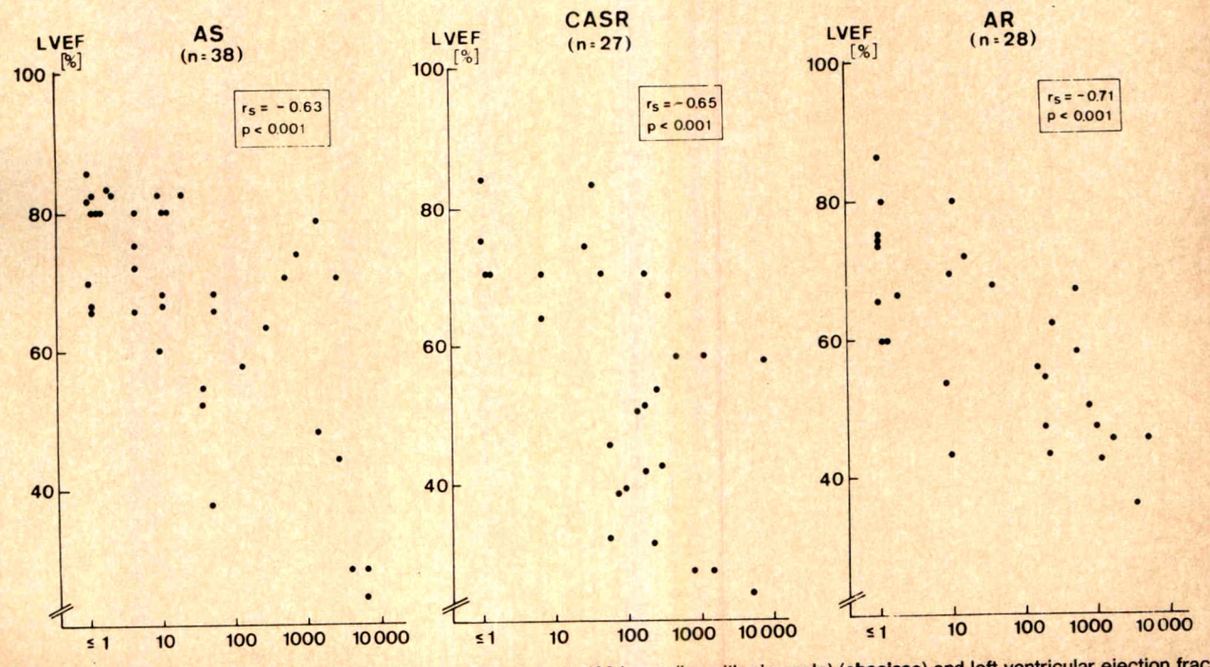

FIGURE 1. Relation between incidence of ventricular premature beats/22 hours (logarithmic scale) (**abscissa**) and left ventricular ejection fraction (LVEF) (**ordinate**). **Left panel,** 38 patients with aortic stenosis (AS). **Center panel,** 27 patients with combined aortic stenosis and regurgitation (CASR). **Right panel,** 28 patients with aortic regurgitation (AR).

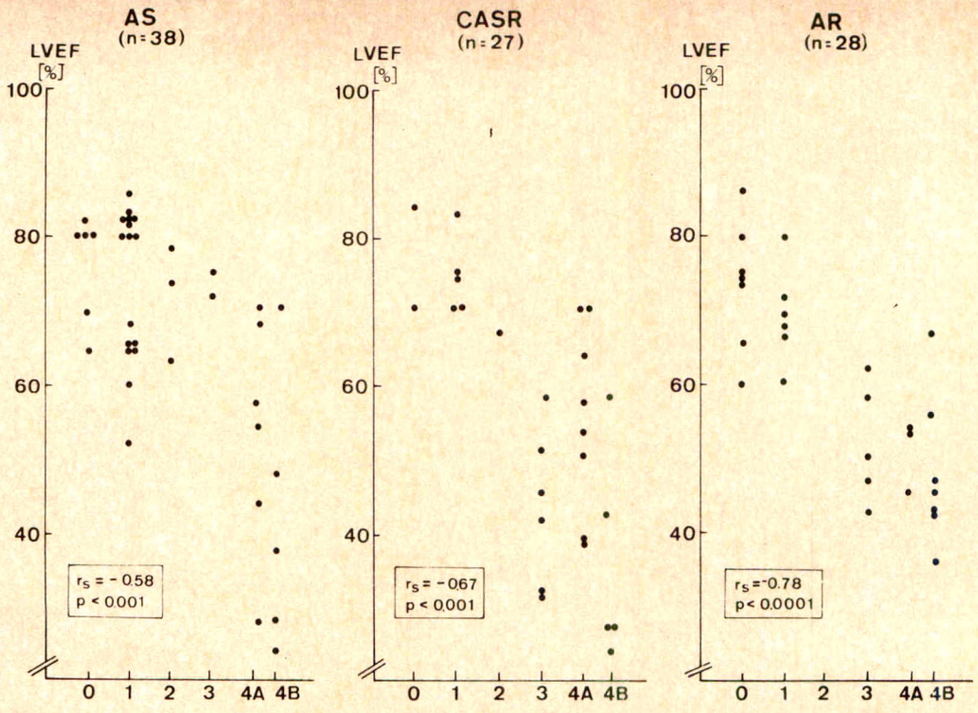

FIGURE 2. Relation between grade of arrhythmia (**abscissa**) and left ventricular ejection fraction (LVEF) (**ordinate**) in 38 patients with aortic stenosis (AS) (**left panel**), 27 patients with combined aortic stenosis and regurgitation (CASR) (**center panel**) and 28 patients with aortic regurgitation (AR) (**right panel**).

tional class, left ventricular end-diastolic pressure, cardiac index, and peak systolic left ventricular wall stress showed no or a weak (r_s <0.50) relation to VPB frequency. In particular, aortic gradient and aortic valve area in patients with AS and the degree of AR in patients with AR showed no correlation with VPB frequency.

Grade of ventricular arrhythmia (Table III): Seventy-eight patients (84%) had ventricular arrhythmias. Forty-four patients had ≤30 VPB in any 1 hour, and 34 patients had >30 VPB in at least 1 hour. Forty-seven (51%) patients had multiform and 32 (34%) had paired VPB. Seventeen (18%) patients had ventricular tachycardia. These differences were insignificant.

Grade of ventricular arrhythmia and left ventricular performance (Fig. 2 and 3): After selecting the highest grade of ventricular arrhythmia for each patient, we found a highly significant inverse correlation between the left ventricular ejection fraction and the grade of arrhythmia in all 3 groups (AS, $r_s = -0.58$; AS and AR, $r_s = -0.67$; AR, $r_s = -0.78$; all $p < 0.001$) (Fig. 2). All 24 patients with an ejection fraction <50% had complex VPB (grades 3 to 4B). A significant relation also was observed between peak systolic left ventricular wall stress and grade of arrhythmia in all 3 groups (AS, $r_s = 0.56$; AS and AR, $r_s = 0.58$; AR, $r_s = 0.57$; all $p < 0.005$) (Fig. 3).

Only weak correlations (r_s <0.50) were found between the highest grade of arrhythmia and the New York Heart Association functional class, left ventricular end-diastolic pressure, and cardiac index in all 3 groups. Particularly, there was no relation between the aortic gradient or aortic valve area and the highest grade of ventricular arrhythmia in patients with AS. The degree

of regurgitation in patients with AR also showed no relation to the highest grade of arrhythmia.

Ventricular tachycardia (Table IV): Table IV summarizes the clinical and ambulatory electrocardiographic findings in the 17 patients with ventricular tachycardia. Five patients had AS, 5 had AS and AR, and 7 had AR. Only 4 had syncope, but only Patient 61 had a syncopal episode during ambulatory monitoring. The 17 patients with ventricular tachycardia had a significantly lower left ventricular ejection fraction (42 versus 65%, $p < 0.01$), higher peak systolic left ventricular wall stress (468 versus 362 dynes $\times 10^3/cm^2$, $p < 0.001$), and a higher incidence of VPB (1,825 versus 390 VPB/22 hours, $p < 0.01$) than the 76 patients without ventricular tachycardia. All patients except 2 (Patients 16 and 89) also had paired VPB. Ventricular tachycardia in all except Patient 61 was nonsustained. Four patients had a single episode of ventricular tachycardia only, with a maximum of 5 beats; the longest nonsustained episode of ventricular tachycardia consisted of 12 beats. Long-term follow-up of the surviving 15 patients was not feasible since all underwent operation within 4 weeks.

None of the 93 patients died from heart failure, but 2 patients with ventricular tachycardia died suddenly. Patient 12 had sudden death within minutes at home (witnessed by his wife) while scheduled for operation the following week. The final arrhythmia could not be documented, but sudden death strongly suggests that a ventricular tachyarrhythmia was the reason for this lethal outcome. Patient 61, with severe AS and AR and a left ventricular ejection fraction of 24%, died suddenly in the hospital while awaiting operation. He was sitting and talking to his wife with no apparent anxiety or physical exertion when ventricular tachycardia with a frequency of 180 beats/min resulted in sudden death (Fig. 4).

Discussion

This study indicates that significant ventricular arrhythmias are common in patients with severe aortic valve disease. Left ventricular performance, as assessed by ejection fraction and peak systolic left ventricular

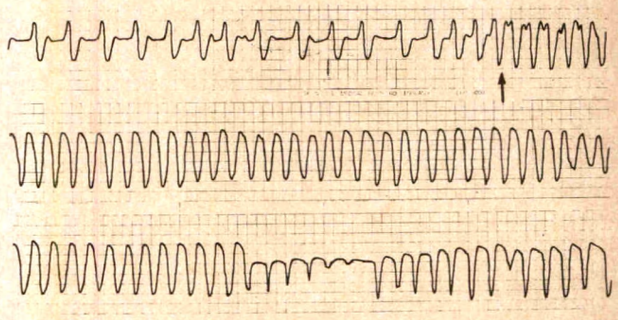

FIGURE 4. Ambulatory electrocardiographic recording at the time of the sudden cardiac death of Patient 61, who had severe combined aortic stenosis and regurgitation and reduced left ventricular function. Ventricular tachycardia developed suddenly (**arrow**), with a rate of 180 beats/min.

AR = aortic regurgitation; AS = aortic stenosis; LVEF = left ventricular ejection fraction; NYHA = New York Heart Association functional class; PSLVWS = peak systolic left ventricular wall stress (dynes $\times 10^3/cm^2$); VPB = ventricular premature beat; VT = ventricular tachycardia.

wall stress, is the major determinant of the occurrence of complex ventricular arrhythmias.

Incidence and severity of ventricular arrhythmias: Frequent and complex ventricular ectopic activity was noted in 55% of the patients evaluated. Furthermore, 18% of the patients had ventricular tachycardia. Two of 17 patients with ventricular tachycardia died suddenly in the time between heart catheterization and their scheduled operations.

There are only a few preliminary studies on preoperative ventricular arrhythmias in patients with aortic valve disease. Kennedy et al[12] studied a small sample of 8 patients with AS and 7 patients with AR and found multiform VPB in 93% and ventricular tachycardia in 47%. They noted that the VPB frequency is rather low in patients with AS.

In another preliminary study, Schilling et al[13] described a marked prevalence of complex VPB in patients with aortic valve disease. In their study of 38 patients with AR, the grade of ventricular arrhythmia correlated with cardiac index, left ventricular end-diastolic pressure, and end-diastolic diameter.

Hochreiter et al[14] studied 28 patients with severe AR and could not detect a significant relation between the occurrence of complex VPB and left ventricular ejection fraction, although 10 of their 28 patients had multiform or repetitive ventricular arrhythmias. That only 38% of the patients exhibited complex VPB may be a hint that the patient group of this study is not comparable to our sample, in which 55% of patients with AR had complex VPB.

Klein et al[15] postulated that complex VPB in patients with AS may be associated with increased left ventricular wall stress. In 10 of their 26 patients with critical AS and complex VPB, they found increased left ventricular wall stress, whereas the mean ejection fraction did not differ in patients with grades 0 to 2 and grades 3 to 4B arrhythmias.

Role of left ventricular performance: In patients who survived myocardial infarction, a relation between left ventricular ejection fraction and the occurrence of complex ventricular arrhythmias has been demonstrated. Several investigators[16–18] have observed that the severity of ventricular arrhythmias may be related to both the number of stenotic coronary vessels and the extent of left ventricular dysfunction. The extent of fibrotic replacement of myocardium seems to be a major determinant of ventricular arrhythmias in patients who have had a myocardial infarction.

Our data indicate that in patients with AS, a high transvalvular gradient may not lead to complex ventricular arrhythmias as long as left ventricular performance is normal. The same applies to patients with AR: a high regurgitation volume may be tolerated by a normal left ventricle without the developmment of complex arrhythmias. However, there is considerable overlap: 23 (33%) of 69 patients with an ejection fraction >50% had complex VPB. This overlap was smaller in patients with AS than in patients with significant AR, indicating that an ejection fraction of 50% may already be a sign of impaired left ventricular function in patients with severe AR.[19]

In contrast, only 6 (25%) of 24 patients with an ejection fraction <50% had <100 VPB/22 hours, and all had complex VPB (grades 3 to 4B). Only 4 (9%) of all 47 patients with complex VPB had a peak systolic left ventricular wall stress <300 dynes $\times 10^3/cm^2$. Thus, reduced ejection fraction and high left ventricular wall

stess appear to be the major determinants of severe ventricular arrhythmia in aortic valve disease. In our study, these relations were demonstrated by highly significant correlation coefficients.

It has been shown that considerable changes in ultrastructure and augmentation of subendocardial fibrosis occur in patients with aortic valve disease with severe impairment of left ventricular performance.[20,21] These changes have been interpreted as morphologic correlates of myocardial ischemia and may be related to the occurrence of ventricular arrhythmias in these patients.

Significance of ventricular arrhythmias: Frequent and repetitive ventricular arrhythmias are associated with an increased risk of sudden cardiac death in patients who survived myocardial infarction.[22–25] In patients with aortic valve disease, it is unknown whether the occurrence of complex ventricular arrhythmias carries the same adverse implications. In patients with unoperated AS, the mortality rate due to sudden death has been found to be 15 to 20%, and of these patients only 3 to 5% were asymptomatic.[1] Sudden cardiac death also may occur in patients with significant AR (Patient 61). Schwartz et al[2] suggested a large left ventricle, a significant transvalvular gradient, and fibrotic replacement of the heart muscle as predisposing factors for syncope and sudden death in patients with AS. The sudden death of 2 of 17 patients with ventricular tachycardia in this study and the high incidence of sudden death reported by others add strong support to the thesis that ventricular tachyarrhythmias play a significant role in determining the eventual mortality rate. Since most patients are surgical candidates, a prospective study to answer this question adequately is impossible. Seven patients had bundle branch block, but no bradycardias were observed as another possible mechanism of sudden death.

Methodologic problems: The main point of criticism against the grading system for ventricular arrhythmias[9] is that a person can be assigned only to 1 grade and that the frequency of VPB is not taken into account in the higher grades 3 to 4B. To overcome these problems, we evaluated the recordings with respect to (1) number of VPB, and (2) the grade of arrhythmias. All grades of arrhythmia detected in each patient were listed. Thus, the total number of patients is >93 and the total percentage is >100% in Table III. Both a high incidence of VPB and a high grade of ventricular arrhythmia may identify patients with reduced left ventricular function, confirming that a higher grade of arrhythmia is usually associated with a higher incidence of VPB.

Variations in the frequency of uniform and complex ventricular arrhythmias are well documented.[26,27] Only 3 of 12 patients with 2 consecutive 24-hour recordings remained in the same grade of arrhythmia (Table I). This is mainly due to the low frequency of paired VPB and ventricular tachycardia, which were detected only once or twice in some patients during 24 hours. It is surprising that only 1 of 12 patients with 2 recordings changed from grade 0 to 2 to grade 3 to 4B. Thus, the separation of patients in grades 0 to 2 and grades 3 to 4B according to the results of ambulatory monitoring appears to be sufficiently stable. As demonstrated in Figure 2, these 2 classifications of arrhythmia best separate patients with normal and reduced left ventricular function in daily routine monitoring. However, the considerable overlap, also shown in Figure 2, has to be taken into account.

Left Ventricular Response to Isometric Exercise and Its Value in Predicting the Change in Ventricular Function After Mitral Valve Replacement for Mitral Regurgitation

HEIKKI V. HUIKURI, MD, MARKKU J. IKÄHEIMO, MD,
MARKKU M. K. LINNALUOTO, MSc, and JUHA T. TAKKUNEN, MD

Reduced left ventricular (LV) afterload and its effect on the resting ejection fraction may lead to overestimation of LV function in mitral regurgitation (MR). To evaluate LV function during increased afterload of the heart, an isometric handgrip test was performed during cardiac catheterization in 15 patients with mitral regurgitation (MR group) and in 9 normal subjects (normal group). Twelve months after successful mitral valve replacement (MVR) the patients were recatheterized, and the value of preoperative stress testing in predicting the change in resting ventricular function after surgery was estimated.

Isometric exercise caused an increase in end-systolic wall stress, a measure of ventricular afterload, in both the MR group and the control group ($p < 0.001$). The ejection fraction remained unchanged in the control group, but decreased from 0.58 ± 0.08 to 0.53 ± 0.08 in the MR group ($p < 0.001$). After MVR, end-systolic wall stress increased significantly ($p < 0.001$) and the ejection fraction decreased from 0.58 ± 0.05 to 0.51 ± 0.1 ($p < 0.05$). A positive correlation existed between the change in the ejection fraction during preoperative stress testing and the change in the resting ejection fraction after MVR ($r = 0.65$, $p < 0.01$). In 8 patients whose resting ejection fraction was within normal limits (>0.55) preoperatively, the ejection fraction was depressed (<0.55) 1 year after surgery. In all but 1 of these patients the isometric exercise revealed the reduced ventricular response to afterload stress preoperatively (decrease of the ejection fraction >0.03 during exercise). Therefore, the isometric exercise-induced change in LV function appears to predict the influence of MVR on LV function.

The ejection fraction is used to quantitate left ventricular (LV) function in patients with heart disease. However, it may lead to overestimation of myocardial function in patients with mitral regurgitation (MR).[1] The regurgitant mitral valve reduces LV afterload, allowing a greater part of the contractile force of the heart to be expended in shortening myocardial fibers than in developing tension.[2,3] The systolic unloading often leads to a normal ejection fraction despite myocardial dysfunction. The imposition of a competent mitral valve increases ventricular afterload and results in a decrease in the ejection fraction.[4–6]

Isometric exercise increases the afterload of the heart and is useful as a stress test.[7–9] The purpose of our study was to evaluate by invasive methods whether isometric exercise could unmask LV dysfunction in patients with MR. Second, we aimed to examine the value of an afterload stress test in predicting the influence of mitral valve replacement (MVR) on ventricular function.

Methods

Fifteen patients with moderate or severe MR (3+/4 or 4+/4 MR on LV cineangiography) and 9 normal subjects participated in the study. The patients were studied by cardiac catheterization preoperatively and 12 months after MVR. Patients with concomitant aortic valve disease (>10 mm Hg systolic gradient across aortic valve or clinical signs of aortic regurgitation, or both) were excluded. Patients with significant mitral stenosis (mitral valve area <2.0 cm^2) were also excluded. No regional wall abnormalities were seen on cineangiography in patients with MR. Five normal subjects underwent cardiac catheterization because of chest pain and 4 because of suspected intracardiac shunt. They were considered normal because the ejection fraction was >0.60, they showed no regional abnormalities in wall motion on cineangiography, LV end-diastolic pressure was ≤13 mm Hg, and

they had no coronary disease, intracardiac shunt, or valve lesion.

The mean age of the MR group was 50 ± 5 years and consisted of 7 women and 8 men. The mean age of the control group was 40 ± 11 years and consisted of 5 women and 4 men. Ten patients in the MR group had atrial fibrillation in both pre- and postoperative studies; other 5 patients and all normal subjects were in sinus rhythm. Ten patients had chronic MR, which was considered the result of rheumatic fever; 3 patients had ruptured chordae tendineae; and 2 patients were considered to have a "floppy" mitral valve. All patients in the MR group were receiving digitalis and diuretic therapy during pre- and postoperative studies. No patient was receiving beta-blocking or vasodilating agents. In 11 patients the valve was replaced by a Björk-Shiley disc valve prosthesis and in 4 patients by a St Jude's medical valve prosthesis.

Pre- and postoperative invasive studies: Pre- and postoperative right- and left-sided cardiac catheterization was performed through the cubital vein and the brachial artery. Right atrial, pulmonary, and pulmonary capillary wedge pressure was recorded with a Statham P23Ia transducer. Left ventricular pressure was recorded with a high-fidelity Millar tip-transducer. Its pressures were matched against fluid-filled luminal pressures. A data acquisition system (Hewlett-Packard 5600B) was used for the standard recording of pressure. Selective biplane LV cineangiography was performed in the 45° right anterior oblique position. In normal subjects with chest pain, coronary angiography was performed by the Judkins technique. In the MR group neither coronary angiography nor coronary bypass surgery was performed.

Isometric exercise tests: After preoperative ventriculography, LV pressure was recorded until a return to baseline levels. Thereafter, at least 20 minutes after resting cineangiography, the patients were asked to perform a handgrip test. Each patient's maximal voluntary handgrip contraction was determined as the average of 2 or 3 maximal attempts using a hand dynamometer (Martin, Germany) held in the left hand. After calculation of the maximal voluntary contraction, the patients were asked to perform a sustained handgrip of 30% of the mean maximal voluntary contraction. The patients were watched carefully to avoid the Valsalva maneuver. During sustained grip, LV pressure, heart rate, and cardiac output by thermodilution were determined every minute for 4 minutes. After 4 minutes of handgrip and with the patients still performing the grip, LV cineangiography was again performed.

Measurements: Left ventricular volumes were measured from 1 or 2 representative beats and the postextrasystolic beats were discarded. The rate of filming was 50 frames/s. The volume curve was obtained by tracing each frame throughout 1 or 2 cardiac cycles. In patients with atrial fibrillation, the volume measurements were taken on beats that most closely approximated the average R-R interval for the basal ventricular response. In postoperative angiograms the cycle length was chosen for analysis, which mostly resembled that of the preoperative cycle. The greatest individual variation in R-R cycle lengths in pre- and postoperative volume measurements was 0.14 second. The contours of the left ventricle were digitized at biplane with a sonic pen on the projection screen using the Hewlett-Packard 5600B and the biplane area-length method for volume.[10] Regression equations previously established in our laboratory were used.[11] The LV pressure curve was recorded simultaneously with the angiogram at a paper speed of 150 mm/s. The mitral valve area was calculated

from Gorlin's modified formula as described by Hammermeister et al.[12] The flow of the orifice was measured from the total LV stroke volume. The LV mass was calculated as described by Rackley et al.[13] The mitral regurgitant fraction was measured by subtracting the stroke volume, determined by the Fick method and by thermodilution during exercise, from the total LV stroke volume. Circumferential wall stress was estimated from the following formula:[14] $(PR_i/H)(a_h)[1 - 1/2(R_i/B)]^2$, where p = LV pressure, R_i = minor semiaxis, B = major semiaxis, H = wall thickness, and $a_h = (r_m + H/2)$, $r_m = B^2/R_i$. End-systolic wall stress was estimated by measuring the pressure, minor and major semiaxes, and the wall thickness at end-systole. End-systole was determined at the point where volume was at a minimum and wall thickness at a maximum. Volume and wall thickness were determined at 20-ms intervals throughout 1 or 2 cardiac cycles by tracing each frame.

p values determined with paired *t* test.
EF = ejection fraction; EDVI = end-diastolic volume index; ESVI = end-systolic volume index; ESWS = end-systolic wall stress; SD = standard deviation.

Calculations: Statistical analysis was performed using the paired *t* test in comparing individual data at rest with data during exercise and by comparing individual changes between pre- and postoperative data. The standard *t* test was used to compare changes in different groups. A standard correlation coefficient was used in estimating correlations.

Results

Clinical data: Preoperatively, 4 patients were in functional class IV, 10 in class III, and 1 in class II. No patient had a history of angina pectoris. The mean duration of symptoms was 53 ± 37 months. The mean mitral regurgitant fraction was 0.47 ± 0.13. After MVR all patients showed functional improvement; 11 patients were in class II and 4 in class I.

Preoperative hemodynamic and angiographic data at rest and during isometric exercise: Individual hemodynamic data at rest and during exercise in both the MR and the control group are presented in Table I. Heart rate and LV peak systolic pressure increased significantly in both groups, but the end-diastolic pressure remained unchanged during exercise.

Individual preoperative angiographic data at rest and during exercise are presented in Table II. The end-systolic volume increased in the MR group but remained unchanged in the control group. The end-diastolic volume remained unchanged in both groups during exercise. The ejection fraction decreased significantly in the MR group while remaining unchanged in the control group (Fig. 1). End-systolic wall stress increased significantly in both groups during handgrip exercise (Fig. 2). End-systolic wall stress/end-systolic volume index ratio remained unchanged in the MR group whereas it increased significantly in the control group during exercise. The mitral regurgitant fraction increased moderately but not significantly during exercise (0.47 ± 0.13 at rest, 0.53 ± 0.18 during exercise; difference not significant [NS]).

Pre- and postoperative hemodynamic and angiographic data: Individual angiographic data pre- and postoperatively are presented in Table III. End-systolic volume remained unchanged, but end-diastolic volume decreased significantly after surgery. The ejection fraction decreased (Fig. 3), but the end-systolic wall stress/end-systolic volume index ratio increased after MVR. End-systolic wall stress increased from 159 ± 36 to 223 ± 67 g/m² ($p < 0.001$) after MVR. The LV mass index decreased from 130 ± 47 to 111 ± 35 g/m² ($p < 0.05$). Mean pulmonary artery pressure decreased from 33 ± 13 to 22 ± 6 mm Hg ($p < 0.005$) and mean pulmonary capillary wedge pressure from 22 ± 5 to 13 ± 3 mm Hg ($p < 0.001$) after surgery. The cardiac index remained unchanged (3.0 liters/m² preoperatively, 2.9 postoperatively; NS).

Correlations between pre- and postoperative measures of LV function: There was no correlation between pre- and postoperative resting ejection fraction ($r = 0.11$, NS) or between preoperative ejection fraction and postoperative end-systolic wall stress/end-systolic volume index ratio ($r = 0.23$, NS). The preoperative

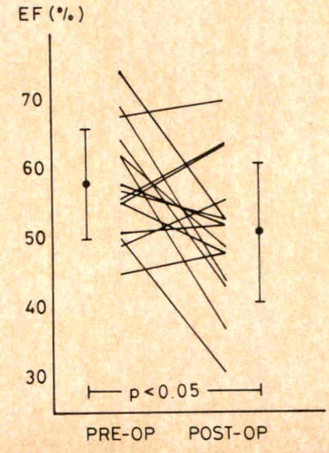

FIGURE 3. Preoperative (PRE-OP) and postoperative (POST-OP) ejection fraction (EF) in patients with mitral regurgitation.

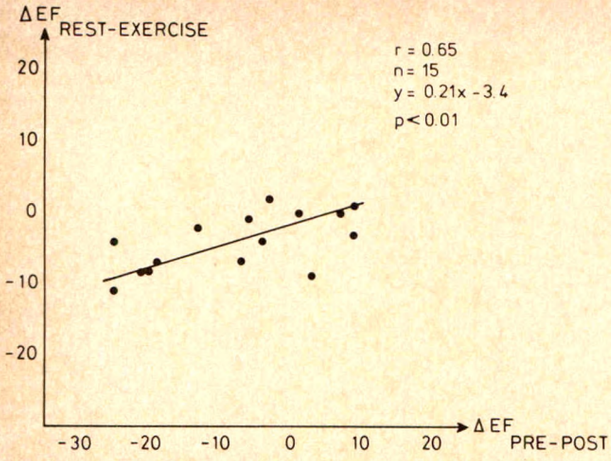

FIGURE 4. Correlation between the change in ejection fraction in percent units during isometric exercise test ($\Delta EF_{REST-EXERCISE}$) and the change in EF in percent units after mitral valve replacement ($\Delta EF_{PRE-POST}$).

resting ratio between end-systolic wall stress and end-systolic volume index did not correlate with the postoperative resting ejection fraction (r = 0.37, NS). However, a correlation existed between the resting pre- and postoperative end-systolic wall stress/end-systolic volume ratio (r = 0.56, p <0.05). The change in the ejection fraction during exercise correlated well with the change in the resting ejection fraction after surgery (r = 0.65, p <0.01) (Fig. 4) and even better with the change in the resting end-systolic wall stress/end-systolic volume index ratio after surgery (r = 0.75, p <0.001). The correlation between the preoperative resting ejection fraction and the preoperative resting ratio between end-systolic wall stress/end-systolic volume index was poor (r = 0.43, NS). However, after MVR the resting ejection fraction and the resting end-systolic wall stress/end-systolic volume index ratio correlated well with each other (r = 0.78, p <0.001). In 8 patients whose ejection fraction preoperatively was within the normal limits (>0.55), the ejection fraction decreased below 0.55 after surgery. In all but 1 of these patients the ejection fraction decreased >3 percent units during isometric exercise preoperatively, revealing the reduced ventricular response to afterload stress. In 4 patients the end-systolic wall stress/end-systolic volume index ratio decreased after surgery. In these 4 patients the ejection fraction also decreased significantly during isometric exercise preoperatively (>3 percent units).

Discussion

Isometric handgrip exercise has been used to evaluate LV functional reserves in various cardiovascular disorders.[7–9] In the present study we evaluated the ventricular response to isometric exercise in patients with MR and in normal subjects. The theoretical basis for using handgrip exercise as a stress test was the fact that systolic afterload is reduced in MR.[2,3] Increasing the systolic load of the left ventricle by handgrip exercise might reveal latent LV dysfunction and might also simulate the effect of a competent mitral valve prosthesis on ventricular afterload.

Ventricular response to isometric exercise in normal subjects and in patients with MR: The end-systolic volume and the ejection fraction remained unchanged during the afterload stress caused by exercise in normal subjects, indicating increased contractility of the left ventricle in the normal heart. Augmentation of systolic ventricular function during isometric exercise in normal subjects has also been demonstrated in previous studies.[15,16] In most patients with MR the exercise resulted in an increase in end-systolic volume and a decrease in ejection fraction. The increased heart rate probably caused the end-diastolic volume to remain unchanged; otherwise, the afterload stress might have increased the mitral regurgitant fraction and the preload of the left ventricle.

Isometric exercise unmasked the depressed systolic function in many patients with a normal ejection fraction at rest. Previous studies have shown that the resting ejection fraction may remain normal despite depressed myocardial contractility in MR.[1] The lack of correlation between the resting ejection fraction and the resting end-systolic wall stress/end-systolic volume index ratio, which is nearly independent of the loading conditions of the heart,[17] suggests that the ejection fraction at rest may be an invalid index in quantitating the ventricular function in MR.

Correlation between the change in ventricular function during exercise and that after surgery: Of clinical interest was the finding that the change in ejection fraction during the preoperative afterload stress predicted the change in ventricular function after MVR. The decrease in ejection fraction during preoperative exercise test was mainly due to the increase in end-systolic volume. The decrease in ejection fraction after surgery depended mainly on the decrease in end-diastolic volume without a concomitant decrease in end-systolic volume. In other volume overload states, as in aortic regurgitation, in which ventricular afterload is not significantly reduced preoperatively, the abolition of volume overloading results in a decrease in both end-diastolic and end-systolic volume.[18] In patients with MR, despite abolition of volume overloading, the increased afterload caused by the mitral valve[19] results in unchanged end-systolic volume. Our data indicate that acute afterload stress makes it possible to predict the degree to which the myocardium is able to tolerate the long-term influence of afterload stress caused by MVR.

The end-systolic wall stress/end-systolic volume index ratio, which was recently shown to predict the clinical outcome after MVR,[20] had some predictive value also in terms of postoperative ventricular function. The ratio of end-systolic wall stress/end-systolic volume index may also depend on the duration and extent of the valvular lesion, not only on myocardial function. The reliable quantitation of this ratio requires highly invasive methods and is not suitable for serial preoperative measurements. The LV response to isometric exercise can easily be quantitated also by noninvasive methods, such as echocardiography[21] and radionuclide

angiography,[22] and so offers the possibility of monitoring the ventricular response to afterload stress.

Possible methodologic limitations of the study: Atrial fibrillation may affect quantitation of the ventricular volumes and the ejection fraction. As the individual cycle-length was chosen as equal as possible in pre- and postoperative angiograms, we do not think that cycle-length variation was of major significance in the results. The variations in determining the end-systolic point may affect the estimation of the end-systolic wall stress, as the pressure curve declines rapidly near end-systole in MR. We tried to eliminate the possible variation in determining the end-systole by measuring volumes and wall thickness at 20-ms intervals; moreover, as we had simultaneous pressure recordings with the angiogram, we do not believe that the changes seen in end-systolic wall stress during exercise and after surgery were due to variations in the end-systolic point. Finally, we did not perform coronary arteriography in patients with MR. Because ischemic heart disease is not exceptionally common in patients with MR[3] and because no patient had angina pectoris, we do not think that the reduced ventricular response to exercise was due to coronary artery disease.

Implications: All of our patients had functional improvement after surgery. Therefore, our results do not provide data on the value of preoperative isometric exercise testing in predicting the postoperative clinical outcome. However, evaluation of the LV response to isometric exercise can predict changes in ventricular function after surgery and thus may provide information helpful in making therapeutic decisions regarding valve replacement in patients with MR.

Preoperative Invasive Testing in Mitral Stenosis: Indications Based on Assessment of Diagnostic Yield

MARC K. EFFRON, MD, EDWIN L. ALDERMAN, MD, and RICHARD L. POPP, MD

The role of preoperative invasive testing in mitral stenosis was assessed in 82 patients undergoing cardiac catheterization for isolated mitral stenosis. The patients were diagnosed by physical examination and echocardiography and were considered for surgical treatment primarily to relieve dyspnea. They had no precordial murmur attributable to an aortic valvular lesion and had no history of chest pain. The presence of mitral stenosis was confirmed at catheterization in all patients. All 38 patients in New York Heart Association functional class III and 8 of 9 patients in class IV had hemodynamic confirmation of mitral disease warranting operation. Although a mitral gradient was present in all 35 patients in class II, operation was not recommended in 9 (26%) of 35 with normal or mildly elevated pulmonary arterial wedge pressure. Invasive testing did not increase preoperative knowledge of aortic, tricuspid, or pulmonary valvular lesions which required surgical treatment. Coronary arteriography was performed in 44 patients (54%) and identified 4 patients with luminal narrowing (>70% diameter reduction) affecting 1 or 2 arteries. These results suggest that preoperative invasive testing in patients with mitral stenosis is unnecessary when symptoms are moderate to severe and clinical evidence of aortic valvular or coronary artery disease is absent. However, preoperative cardiac catheterization is indicated in patients with mild symptoms to avoid unnecessary or premature mitral valve operations.

The risk and rising cost of cardiac catheterization, at a time of improvements in noninvasive imaging, have prompted reconsideration of the need to use invasive tests to evaluate patients with valvular heart disease. Clinical course and short-term survival after valve replacement have been similar whether or not preoperative cardiac catheterization was performed.[1] Thus, editorial recommendations against routine invasive study have been made.[2,3] However, analysis of outcome only in patients undergoing surgical treatment may not identify patients with hemodynamically insignificant disease whose operations were unnecessary or premature. Such operations may be avoided by routine cardiac catheterization of operative candidates. Invasive testing may additionally serve to assess operative risk and has been advocated for the detection of asymptomatic coronary artery disease.[4] Moreover, because of different clinical profiles in patients with different types of valvular lesions, global generalizations about indications for invasive diagnostic evaluations may not be valid.

We examined in detail the role of cardiac catheterization in patients with mitral stenosis (MS) because of the relatively distinct and specific clinical and echocardiographic features of this disease. Other investigators[5] have specifically questioned the need for invasive procedures in MS. A small prospective study of decision-making in patients with MS suggested that management decisions based on clinical and noninvasive findings are not altered by subsequent invasive testing.[6] In patients with MS considered candidates for mitral operation, we report the results of routine preoperative cardiac catheterization and the extent to which these results contribute to clinical management.

Methods

A total of 167 consecutive patients undergoing echocardiographic and invasive evaluation of suspected MS between March 1974 and July 1981 at Stanford Medical Center were retrospectively identified using a computer-based data bank. During this period, no patients evaluated by the Stanford cardiology service had surgical treatment for MS without preceding cardiac catheterization. Five patients who were considered operative candidates primarily for treatment of arrhythmia or recurrent embolization were excluded. Before invasive testing, all patients in the study were considered candidates for mitral valve operation primarily for relief of

dyspnea and were assigned to New York Heart Association functional class II, III, or IV (class II, symptoms with ordinary activity; class III, symptoms with less than ordinary activity; class IV, symptoms at rest). All patients received physician interview, physical examination confirming the presence of a diastolic murmur suggestive of MS, electrocardiography, and chest roentgenography. Before cardiac catheterization, each had M-mode echocardiography confirming the presence of a rheumatic mitral valve. Two-dimensional echocardiography was performed during the last 31 months of the 84-month study period.

One hundred sixty-two operative candidates with MS were identified by the foregoing criteria. Additional criteria were then applied to distinguish patients with relatively isolated mitral disease from those with clinical evidence of other lesions with potential surgical implications (Fig. 1). The 80 patients with other clinically evident lesions included 9 patients with suspected aortic stenosis (any basilar systolic ejection murmur of suspected aortic valve origin), 32 with suspected aortic regurgitation (any diastolic decrescendo murmur attributed to aortic regurgitation), 22 with both suspected aortic stenosis and regurgitation, 2 with prosthetic aortic valves, 3 with a history of angina pectoris, 3 with suspected aortic valvular disease and angina pectoris, 5 with previous myocardial infarction, and single patients with a mitral Carpentier ring, suspected tricuspid stenosis, previously diagnosed alcoholic cardiomyopathy, and suspected subclavian steal syndrome. These patients with aortic valvular disease, coronary artery disease, or less common conditions were excluded from further study. The study group was composed of the remaining 82 patients with clinical and echocardiographic features of MS and included patients with associated mitral, pulmonary, or tricuspid regurgitation.

Cardiac catheterization included hemodynamic measurements during exercise if resting pulmonary artery and pulmonary arterial wedge pressures were normal or mildly elevated. Mitral valve area was determined by the Gorlin formula using Fick cardiac output. The computed mitral valve area was recognized as underestimated in moderate or severe mitral regurgitation. Left ventricular angiography was performed in all except 1 individual. All patients had no clinical evidence of coronary artery disease. Because this study covered a broad time span, coronary arteriography was not performed with a consistent age criterion but was obtained in 54% of patients.

The 82 study patients were characterized by age, sex, severity of symptoms, history of previous commissurotomy, clinically evident mitral regurgitation, ancillary echocardiographic findings, results of cardiac catheterization and angiography, final therapeutic decisions, and in-hospital operative mortality. Patients with evidence of moderate to severe mitral regurgitation before catheterization were retrospectively identified by the presence of an apical holosystolic murmur of greater than grade 1 intensity (scale of 6) and at least 2 of 3 other criteria: left ventricular enlargement on precordial examination, left ventricular hypertrophy on electrocardiography without concomitant systemic hypertension, and diastolic left ventricular internal dimension >5.7 cm on M-mode echocardiography.

Results

Fourteen men and 68 women comprised the study group. Patients ranged in age from 21 to 75 years, with 77% between the ages of 40 and 70. Twenty-three pa-

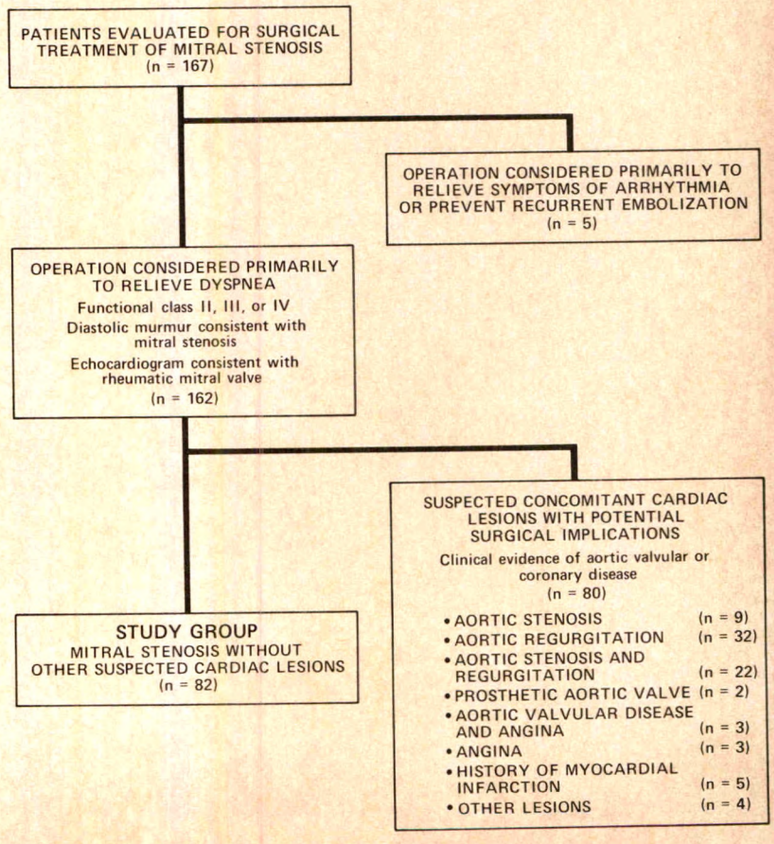

FIGURE 1. Diagram of study group selection among all patients considered for surgical treatment of mitral stenosis. Reasons for inclusion or exclusion are depicted with the number of patients in each category. The study group included cases of clinically evident mitral, pulmonary, and tricuspid regurgitation. Criteria for suspicion of aortic valvular disease are described in the text.

tients had mitral commissurotomy 2 to 24 years before reevaluation.

Of the 82 patients, 10 fulfilled the clinical criteria for moderate to severe mitral regurgitation. Five of these had moderate to severe mitral regurgitation by angiography (grade 3 to 4 on a scale of 4), and in 5 it was mild or absent. An additional 5 patients who did not meet the clinical criteria displayed moderate to severe mitral regurgitation angiographically. Confirmation or exclusion of high-grade mitral regurgitation by angiography did not alter subsequent management, as all of these patients had mitral valve replacement irrespective of the degree of mitral regurgitation. Because patients with high-grade mitral regurgitation all had mitral operations and could not reliably be distinguished clinically from patients with predominant valvular stenosis, all patients were grouped together for further analysis.

Figure 2 depicts the relation of severity of symptoms, calculated mitral valve area, and the final decision for or against surgical treatment. Eighty-nine percent of patients were in New York Heart Association functional class II or III. Although MS was confirmed in all patients, the calculated mitral valve area showed a wide range within each class and overlap between classes. All 38 patients in class III and 8 of 9 patients in class IV had mitral valve disease judged to be hemodynamically significant at catheterization and to warrant operation. The ninth patient in class IV had mild hemodynamic abnormalities disproportionate to the clinical classification, and surgery was not recommended. This patient complained of general fatigue as well as dyspnea, and a cardiac or pulmonary basis for the degree of disability could not be identified. One of the other 8 patients in class IV did not receive a final recommendation for surgical treatment because of poor left ventricular function, as will be discussed.

Ten patients with findings of mild mitral disease on cardiac catheterization were not referred for operation. Five of these had previous commissurotomy. The calculated mitral valve area was <1.5 cm^2 (range 0.8 to 1.4) in 5 of the 10 patients and ≥ 1.5 cm^2 (range 1.5 to 1.9) in 5. One of the 10 patients was in class IV and had a resting pulmonary arterial wedge pressure of 15 mm Hg. The other 9 patients were in class II and comprised 26% of the 35 class II patients. These 9 patients had resting pulmonary arterial wedge pressure <14 mm Hg (range 8 to 13) with an increase to ≤ 25 mm Hg (range 13 to 25) during exercise. Their pulmonary vascular resistance was <200 dynes·s·cm^{-5}. Of the remaining 26 patients in class II, who were advised to have a mitral operation, 8 had resting pulmonary arterial wedge pressure <14 mm Hg (range 11 to 13) which increased with exercise to ≥ 22 mm Hg (range 22 to 34).

Surgical treatment was recommended in 71 patients, and 69 patients had mitral operations. Mitral valve replacement with a porcine heterograft bioprosthesis was performed in 65 patients and mitral commissurotomy in 4. Two other patients decided not to undergo recommended operations. Six patients with minimal mitral calcification and low-grade mitral regurgitation on angiography were regarded as candidates for commissurotomy. However, final decisions between commissurotomy and valve replacement were made after direct intraoperative inspection of the mitral apparatus, leading to valve replacement in 2 of these patients.

Tricuspid regurgitation was clinically suspected in 7 patients and hemodynamically confirmed in 6. No other cases of moderate or severe tricuspid regurgitation were discovered on catheterization. Intraoperative assessment led to tricuspid operations in 4 of these pa-

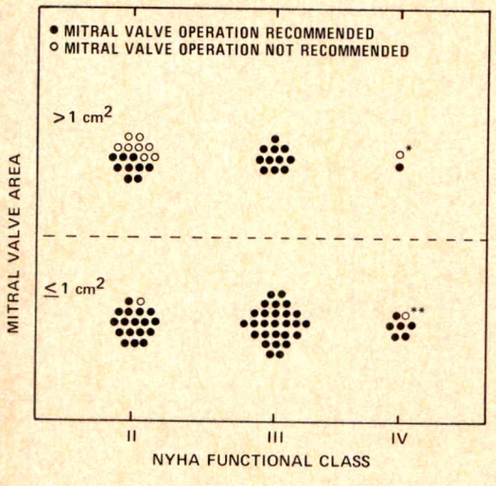

FIGURE 2. Relation of symptom severity by New York Heart Association (NYHA) functional classification, calculated mitral valve area, and final decision for or against surgical treatment of mitral stenosis. **Closed circles** represent patients who received a recommendation for operation; **open circles** represent patients who did not receive a recommendation for operation. For 1 patient (**) in class IV, surgical treatment was precluded by severe left ventricular dysfunction. Other patients who did not receive a recommendation for operation had normal or mildly elevated pulmonary arterial wedge pressure, including 1 patient (*) in class IV with a mitral valve area of 1.6 cm^2 and a resting pulmonary arterial wedge pressure of 15 mm Hg.

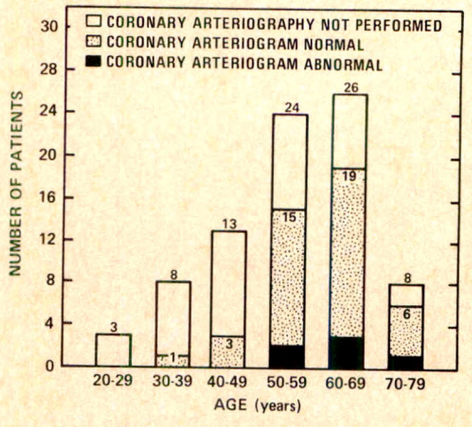

FIGURE 3. Age distribution by decade of patients with mitral stenosis who had cardiac catheterization. Total number of patients in each decade are indicated **above columns**; number of patients who had arteriograms are indicated within **shaded areas. Lightly shaded areas** represent patients who had coronary arteriograms that showed normal vessels or minimal stenoses of <50%; **darkly shaded areas** represent patients who had coronary arteriograms showing stenoses >50%.

tients; 3 underwent tricuspid anuloplasty and 1 received a tricuspid prosthesis for unsuspected primary rheumatic tricuspid disease.

Mild aortic stenosis was discovered at catheterization in 3 patients with peak aortic valve gradients of 17, 22, and 23 mm Hg. Concomitant aortic valve operations were not recommended. Severe pulmonary regurgitation suspected in 1 patient before catheterization was confirmed angiographically, but pulmonary valve surgery was not performed. Pulmonary vascular resistance was elevated above 400 dynes·s·cm^{-5} in 12 patients, but this finding did not alter the decision to operate.

Left ventricular ejection fractions <40% were noted in 4 patients. Those with ejection fractions of 32, 35, and 36% had mitral operations. Operation was not advised for 1 class IV patient with an ejection fraction <20%, for whom surgical risk was judged prohibitively high. Before catheterization, the echocardiogram in this patient showed left ventricular enlargement (left ventricular internal diastolic dimension 6.8 cm) with fractional shortening of 16%.

Coronary arteriography was performed in 44 of the 82 study patients (54%) and most frequently in patients >50 years of age (Fig. 3). Seven of 14 men and 37 of 68 women had arteriography. Thirty-four patients had entirely normal coronary arteries, whereas 4 others had minimal luminal narrowings <50% in major vessels. No left main coronary artery lesions were detected. Stenoses >50% were detected in the remaining 6 patients who ranged in age from 58 to 72 years and comprised 14% of the patients having arteriography. Two patients had moderate stenoses of 55 and 60%, the latter having aortocoronary bypass at mitral surgery. Severe stenoses were detected in 4 patients, comprising 9% of those having arteriography. Of 3 patients with a single stenosis >90%, 2 had coronary bypass during the mitral operation. One patient had 90% stenoses of 2 major vessels and received 2 grafts.

Complications of cardiac catheterization included pulmonary edema in 2 patients in New York Heart Association class III and transient bradycardia and hypotension in 1 patient. There were no fatalities as a direct result of the catheterization. The only hospital death occurred in a patient with moderate mitral regurgitation, normal ventricular function, and normal coronary anatomy preoperatively; this patient died in refractory ventricular failure after cardiopulmonary bypass.

Discussion

Our past practice of performing routine cardiac catheterization in all patients with suspected MS before operation provides an opportunity to examine the extent to which invasive testing contributes to clinical management. Potential contributions of invasive testing include discovery of hemodynamically insignificant disease, occult lesions requiring operative repair at the time of mitral operation, and factors associated with an inordinately high surgical risk.

M-mode echocardiography can confirm the presence of rheumatic mitral valvular disease qualitatively, but the severity of the lesion cannot be dependably predicted.[7] More recently, 2-dimensional echocardiographic measurement of the area of the stenotic mitral valve orifice has been shown to be accurate.[8–11] Because the dyspnea of MS is believed to be a consequence of elevated left atrial and pulmonary capillary pressure,[12] quantitation of the mitral valve area alone may not reflect the true hemodynamic substrate for a patient's symptoms. This is suggested by our catheterization data, which confirm a wide variation of symptoms for specified valve areas. Left atrial pressure elevation is determined by cardiac output and the extent of valvular stenosis, and cardiac output may differ widely between patients with similar valve areas. In some patients, coexisting abnormalities such as mitral regurgitation, ventricular dysfunction, or disproportionate pulmonary hypertension may also contribute to disability. Although the interval between the aortic component of the second heart sound and the mitral opening snap correlates with left atrial and pulmonary capillary pressure, this variable is not dependable enough to designate which patients have disease warranting operation.[13,14]

Ten patients hospitalized for possible mitral operation, but found to have normal or mildly elevated pulmonary arterial wedge pressure at rest and on exercise were not finally recommended for surgical treatment. All but 1 of these patients had symptoms of New York Heart Association functional class II. They did not have an elevated left ventricular diastolic pressure known to mask the hemodynamic findings of MS,[15] nor was their pulmonary vascular resistance substantially elevated. Mitral operation was recommended in 8 patients in class II with a normal or minimally elevated resting pulmonary arterial wedge pressure. These patients generally showed greater increases in pressure during exercise than did patients withheld from operation.

Cardiac catheterization results, most importantly the pulmonary arterial wedge pressure, affected management of these patients with class II symptoms. There was an overlap of hemodynamic values between the patients withheld from operation and those treated surgically, reflecting the fact that a final decision for or against surgical treatment is multifactorial, involving the patient's symptoms and the physician's subjective and objective evaluation. These factors may have contributed to the heterogeneity of management choices among patients with less severe disease. Although it can be proposed that the catheterization data were misleading and that all patients in the present series would still have benefited from surgical treatment, such benefit cannot be reasonably assumed if the hemodynamic measurements were accurate.

In contrast to patients in New York Heart Association functional class II, all patients in class III and all except 1 patient in class IV had findings at cardiac catheterization that confirmed the presence of mitral disease regarded as hemodynamically significant. This suggests that patients in functional classes III and IV can be managed effectively without invasive assessment of the mitral lesion. It is recognized that without invasive study a rare patient in class III or IV may undergo operation for hemodynamically mild mitral disease.

Among our patients in classes III and IV, 1 patient in class IV would have received a premature mitral operation if routine cardiac catheterization had not been performed.

The role of preoperative invasive testing in identifying candidates for mitral commissurotomy is minimal in this series, and only 4 commissurotomies were performed among 69 mitral procedures. The reason may be the older age of the patients and a tendency of the surgical staff at our institution to frequently favor valve replacement with a bioprosthesis. The condition of the mitral apparatus as assessed by direct intraoperative inspection is the final determinant of the type of mitral operation.

Ancillary findings at cardiac catheterization were infrequent and seldom altered surgical management in our series. Physical examination gave adequate evidence of tricuspid regurgitation, which was further assessed intraoperatively. Truly occult aortic valve disease was rare and not severe enough to require treatment in this group. Despite the clinical impression that severe pulmonary hypertension may portend a more prolonged postoperative requirement for mechanical ventilation, knowledge of the pulmonary vascular resistance, in practice, did not alter the decision for or against surgical treatment.

Left ventricular contractility is usually well preserved in patients with MS, although severe left ventricular dysfunction can occur when there is long-standing mitral regurgitation or an independent cardiomyopathy. Because there was only 1 such patient in our study group, routine invasive testing of all patients is not warranted in identifying this small minority. Furthermore, very poor ventricular function may often be suspected on clinical grounds or on echocardiography. Either this suspected subgroup or all patients could currently undergo quantitation of ventricular function by noninvasive imaging.

The occurrence of coronary artery disease in our patients with MS was small. This finding differs from the more common association of coronary artery disease with aortic stenosis.[16,17] The 3 single-vessel and the 1 double-vessel aortocoronary bypass operations performed in this group were of unknown benefit in the absence of chest pain or a history of myocardial infarction. It is unlikely that bypass of a single coronary artery improves long-term prognosis.[18–20] Moreover, randomized controlled studies of coronary artery bypass surgery have included only patients with symptomatic disease.[21,22] Aortocoronary bypass grafting has been advocated in patients difficult to wean from cardiopulmonary bypass after valve replacement.[4] However, the efficacy of this practice has not been demonstrated, and poor ventricular recovery is uncommon in cases of predominant MS.

Some potential limitations of our retrospective study can be noted. Patients may have been excluded from analysis if they were mistakenly not entered into the computer databank, although this is unlikely. The New York Heart Association functional classification used for our patients is partly subjective, not fully reproducible, and influenced by factors other than cardiac disease, yet reflects the symptoms that usually lead patients to evaluation for possible operation.

There was no distinct threshold of hemodynamic abnormality for recommending surgical treatment in class II patients. In practice, it may not be possible to form strict guidelines for these decisions. The decision-making process for our patients relied in part on standard hemodynamic and angiographic results which occasionally may be inaccurate or misleading.[15] Two-dimensional echocardiography is now a widely used technologic advancement that was unavailable during most of the study period; however, the utility of our observations is not altered because the valve area alone was not the primary determinant in recommending surgical treatment.

The appropriateness of surgical treatment can well be demonstrated by objective pre- and postoperative functional assessment, which is not available in this study. We have empirically taken the therapeutic decisions made in this patient group as the basis for evaluating the impact of information obtained at catheterization. Although management decisions are made by a diverse group of physicians, their therapeutic choices reflect a consensus of opinion with regard to the use of clinical and catheterization results.

We have examined the role of cardiac catheterization only in cases of clinically suspected MS with or without mitral, pulmonary, or tricuspid regurgitation. Our conclusions apply only to this subgroup of patients. Patients with primary symptoms of arrhythmia or embolus and patients with concurrently suspected aortic valvular or coronary disease were excluded because of potential surgical indications different from those in the study group.

Recent recommendations for the application of invasive testing in valvular heart disease vary widely and include both strong advocacy of and opposition to routine preoperative cardiac catheterization.[1–4] These editorial statements tend generally to address this issue broadly for patients with all types of valvular lesions. We believe that indications for or against invasive testing will need to be determined separately for specific types of valvular disease. We have assessed the contributions of hemodynamic and angiographic findings in the management of a subgroup of patients with rheumatic MS identified by clinical and noninvasive criteria, who lack clinical evidence of aortic valvular or coronary disease. Our results suggest that preoperative invasive testing is not needed in patients with moderate to severe symptoms, because cardiac catheterization rarely alters the outcome. However, patients with mild symptoms of exertional dyspnea who are considered for operation should undergo cardiac catheterization to identify hemodynamically insignificant mitral disease and thus defer or avoid surgical treatment.

Noninvasive Diagnosis of Aortic and Mitral Valve Disease With Pulsed-Doppler Spectral Analysis

KENT L. RICHARDS, MD, SCOTT R. CANNON, PhD, MICHAEL H. CRAWFORD, MD, and SHERMAN G. SORENSEN, MD

To differentiate normal from abnormal left-sided heart valves, 34 adults (6 normal and 28 abnormal) with 48 valve lesions proved at catheterization were examined using a 3 MHz duplex pulsed Doppler echocardiograph with 2-dimensional verification of sample volume position and on-line display of the Doppler audio spectrum. A uniform protocol was used to position the sample volume for each lesion and to analyze the Doppler spectral data. Intracardiac blood turbulence, manifested by an increased Doppler spectral envelope area, was the noninvasive indicator of disease. The specific lesion present was determined by documenting the intracardiac location and timing of the turbulence. Doppler spectral envelope areas in all normal valve sites were smaller than those measured at the same sites in patients with aortic stenosis, mitral stenosis, and mitral regurgitation ($p < 0.01$). Except for a single patient with minimal aortic regurgitation, spectral envelope area allowed complete separation of patients with valve disease from normal subjects ($p < 0.01$). High sensitivity (97%) and specificity (100%) were noted despite the presence of multiple valve lesions in 67% of the patients. The data demonstrate application of a simple, noninvasive method of acquiring and analyzing Doppler echocardiographic data which allows accurate identification or exclusion of left-sided valve disease in adults, even in the presence of multiple valve lesions.

Cardiac murmurs are common in the adult population. Among patients >40 years of age, identification of significant valvular heart disease is difficult because clinical findings are influenced by associated systemic hypertension, coronary artery disease, systemic arterial disease, and other valvular heart disease.[1–13] Doppler echocardiography allows noninvasive characterization of intracardiac blood velocity patterns. According to the Doppler principle, the difference between the frequency of ultrasound broadcast into the heart and that reflected from moving blood cells (Doppler frequency shift) is proportional to the velocity of the blood cells encountered. The cylinder of ultrasound from which the Doppler signals are reflected traverses many different velocity regions in the heart. Analysis of the sum of the Doppler signals obtained along the entire ultrasound beam does not allow accurate assessment of the pattern of flow at a specific location along the beam. Range gating is required to allow operator selection of the intracardiac location to be sampled. Documentation of the anatomic region sampled (the sample volume position) is accomplished by recording the position of the sample volume on a 2-dimensional image of the heart. Knowledge of both the anatomic location of the sample volume and the characteristics of flow is required to accurately identify valvular heart disease,[14–25] especially when multiple valve lesions are present.

A simple model (Fig. 1) is helpful in understanding the blood velocity patterns near normal, stenotic, and regurgitant valves. Flow through a normal valve is characterized by blood velocities which are near the same direction and magnitude at a given time.[26,27] Because Doppler signals from areas of normal flow are near the same frequency at any time in the cardiac cycle, they are referred to as "narrow-band." As blood enters a stenotic valve, a high-velocity jet forms within and downstream from the orifice. Around and beyond the jet, turbulent flow is characterized by velocities of multiple magnitudes and directions.[26,28–29] Because Doppler signals from areas of turbulence contain many frequencies at a given time, they are referred to as "broad-band." Broad-band signals are absent downstream from normal cardiac valves, but are present beyond and alongside the high-velocity jet produced by stenotic valves.[14–20,23] Similar high-velocity jets and surrounding turbulent regions are noted near regurgitant valves.[14–17,21,22,24,25,30]

In early studies with Doppler, signal analysis was performed by human interpretation of the audio output.[14] Because experience was required to interpret such signals and a graphic record was not available to document findings, this approach did not achieve wide ac-

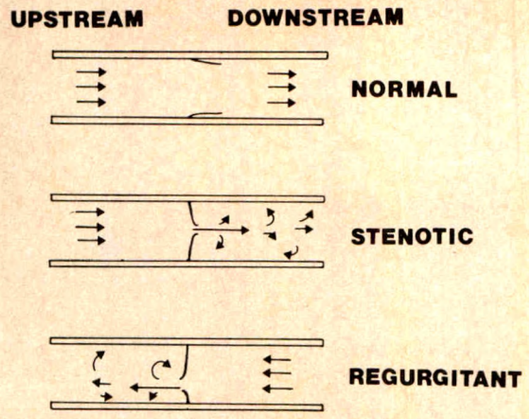

FIGURE 1. Velocity vectors, shown as arrows with magnitude and direction, illustrate blood flow patterns through normal, stenotic, and regurgitant valves. Laminar flow upstream and downstream from a normal valve is represented by parallel vectors of the same magnitude. Turbulent flow downstream from the stenotic valve and upstream from a regurgitant valve is represented by vectors with multiple directions and magnitudes.

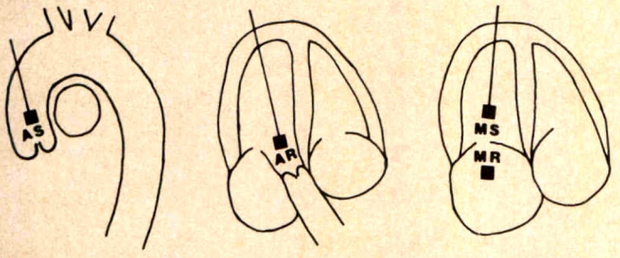

FIGURE 2. Ultrasound beam orientation and sample volume position (black square) used to diagnose aortic stenosis (AS), aortic regurgitation (AR), mitral stenosis (MS), and mitral regurgitation (MR). Suprasternal aortic long-axis view (**left**), apical 4-chamber view at the level of the left ventricular outflows tract (**middle**), and the mitral valve orifice (**right**) are shown.

ceptance. Attempts at graphic representation of Doppler audio signal content by analog and time-interval-histogram records represented improvement,[15–18,21–25] but did not allow actual measurement of spectral broadening. Because both were susceptible to operator-induced artifacts and were less sensitive than techniques providing full spectral analysis,[31–34] they also were not widely used. Recently developed Doppler ultrasonoscopes allow not only on-line analysis of the Doppler audio spectrum, but also accurate documentation of the sample volume position on a 2-dimensional image of the heart. The purpose of this study was to demonstrate the sensitivity and specificity of such duplex Doppler ultrasonoscopes in identifying or excluding valvular heart disease in adults.

Methods

Right and left heart catheterization was the diagnostic standard of reference. The severity of aortic and mitral regurgitation was judged using the angiographic technique described by Grossman and Dexter.[35] Severity of aortic and mitral stenosis was determined by measuring resting mean systolic and diastolic pressure gradients, respectively.

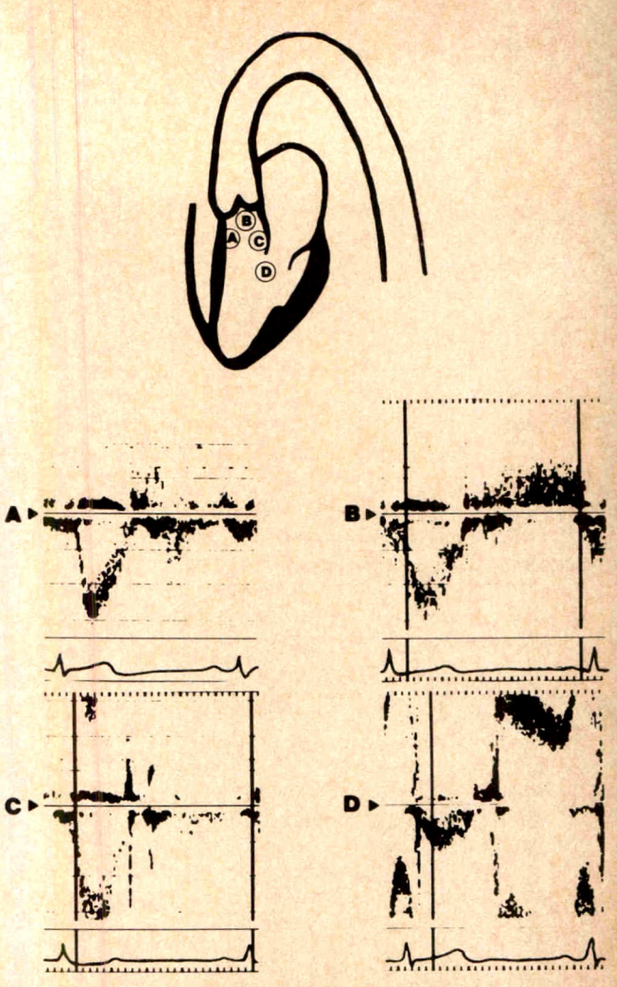

FIGURE 3. Accurate sample volume positioning is required to properly differentiate the various causes of broad spectrum diastolic Doppler signals within the left ventricular outflow tract. The **top panel** shows sample volume positions superimposed on a long-axis parasternal view of the heart. The **bottom panel** shows Doppler spectral tracings corresponding to those sample volume positions. In each spectral tracing, time is on the *x*-axis, Doppler frequency shift is on the *y*-axis, and signal amplitude is displayed as gray-scale on the *z*-axis. The electrocardiogram is shown at the bottom of each spectral tracing: **A,** wall motion artifacts produced by inclusion of the interventricular septum in the sample volume result in transient, high-amplitude artifacts in early and mid-diastole; **B,** aortic regurgitation produces pandiastolic, broad-spectrum signals when the sample volume is positioned within the regurgitant area of turbulence; **C,** mitral valve motion artifacts produced by inclusion of the anterior mitral leaflet in the sample volume result in transient, high-amplitude artifacts in early diastole; **D,** high-frequency, broad spectrum, pandiastolic signals result from placement of the sample volume in the mitral valve orifice in this patient with mitral stenosis.

Each individual was examined using a commercially available duplex 3 MHz pulsed Doppler ultrasonoscope with on-line gray-scale spectral analysis (Advanced Technology Laboratory Mark 5 with 459 Pulsed Doppler Flow Analyzer). Because there is a specific intracardiac anatomic region and cardiac cycle time during which flow disturbance would be anticipated for each valvular lesion, a standard method of examination was used (Fig. 2). To detect aortic stenosis a long-axis view of the aorta was obtained from the suprasternal notch; the sample volume was positioned in the ascending aorta about 4 cm above the aortic cusps. The apical 4-chamber

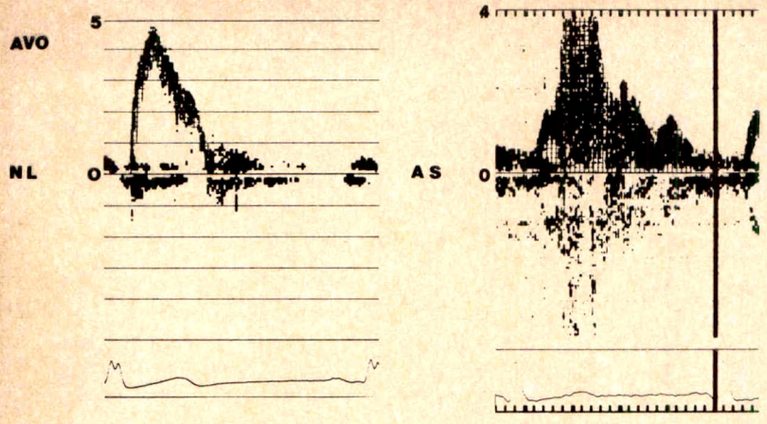

FIGURE 4. Doppler spectral records are shown from the aortic valve outflow tract (AVO) of a normal subject (NL, **left panel**) and a patient with aortic stenosis (AS, **right panel**). Time is on the *x*-axis. Doppler frequency shift (F_D) is on the *y*-axis with baseline as 0 and maximal F_D of 4 and 5 kHz; flow toward the transducer is shown above 0 and flow away is shown below 0. The electrocardiogram is in the **bottom panel.** Note systolic spectral broadening in aortic stenosis. Spectral envelope area measurement is illustrated by **cross-hatching.**

view was used to sample flow in the left ventricular outflow tract in aortic regurgitation, the mitral orifice in mitral stenosis, and the left atrium adjacent to the mitral valve in mitral regurgitation. Careful documentation of the sample volume location by 2-dimensional echocardiography was essential to determine whether broad-band diastolic Doppler signals within the left ventricular outflow tract were produced by wall or valve leaflet motion, mitral stenosis, or aortic regurgitation (Fig. 3). Wall and leaflet artifacts were <100 ms in duration and were noted when such structures were included in the sample volume; the artifact was abolished by minimal changes in beam angle and sample volume depth. The high-velocity, pandiastolic turbulence produced by mitral stenosis was of highest amplitude just downstream from the mitral orifice and never extended into the high left ventricular outflow tract. In contrast, the diastolic turbulence associated with aortic regurgitation was most marked high in the aortic valve inflow tract and diminished as the sample volume was moved toward the mitral valve orifice. Similar careful documentation of sample volume position was also essential to differentiate mitral leaflet-induced artifacts from true mitral regurgitation.

To reduce aliasing, maximal pulse repetition frequency (shallowest depth setting) possible for each examination site was selected. Wall filters were set at 100 Hz; dynamic range was set at 42. Amplifier gain was reduced to a level that would eliminate background noise but allow registration of low-amplitude signals. All spectral records were made at 100 mm/s using a gray-scale black and white strip chart recorder (Advanced Technology, model 130). Time and frequency calibration lines were generated for later reference. As the presence of turbulence was used to indicate valvular disease, the spectral envelope area, a variable that reflects both the degree and the duration of spectral broadening, was measured at each valve site. Figure 4 illustrates measurement of the spectral envelope area defined by the lowest energy systolic signals (cross-hatched area) above an aortic valve in a normal subject (left panel) and in a patient with aortic stenosis (right panel). Spectral envelope areas were measured on the channel toward which abnormal flow would be directed for each valve lesion (forward channel for aortic and mitral stenosis and aortic regurgitation; reverse channel for mitral regurgitation). Only the portion of the cardiac cycle during which abnormal flow would be produced by a given valve lesion was included in the measured spectral envelope area (systole for aortic stenosis and mitral regurgitation; diastole for mitral stenosis and aortic regurgitation). Spectral envelope areas were reported in kilohertz × seconds.

All noninvasive measurements were analyzed by individuals who did not have knowledge of catheterization results at the time of data extraction. Student's *t* test was used to demonstrate differences in mean values for the spectral envelope area between normal and diseased valves at each examination site.

Results

The study group consisted of 34 patients: 6 were normal and 28 had 48 valvular lesions proved at cardiac catheterization. Combined disease of native aortic and mitral valves was noted on catheterization in 4 patients (2 had aortic stenosis, aortic regurgitation, mitral stenosis, and mitral regurgitation; 1 had aortic stenosis, aortic regurgitation and mitral regurgitation; 1 had

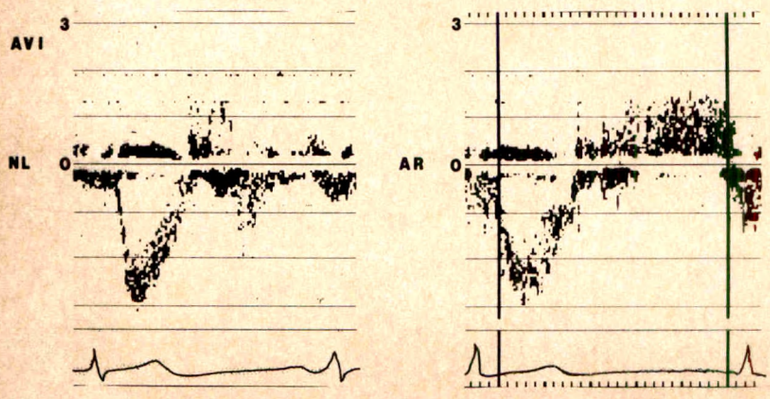

FIGURE 5. Doppler spectral records from the left ventricular outflow tract of a normal subject (NL, **left panel**) and a patient with aortic regurgitation (AR, **right panel**) are shown using the same format as in Figure 4. Note the diastolic spectral broadening in aortic regurgitation.

TABLE I Catheterization and Doppler Echocardiographic Data Summary for Native Valves Only*

Valve Site	n	ΔP	Regurg	Spectral Envelope Area (kHz × s)	p
AS					
Absent	11	0	...	0.11–0.30 (0.26)	<0.01
Present	15	10–103 (36)	...	0.72–1.72 (1.26)	
AR					
Absent	12	...	0	0.13–0.49 (0.32)	<0.01
Present	14	...	1+–3+	0.12–2.58 (1.45)

Present	10	...	1+–4+	0.63–2.07 (1.11)	

* Mean values in parentheses.
AS = aortic stenosis; AR = aortic regurgitation; MS = mitral stenosis; MR = mitral regurgitation; n = number of patients in whom both catheterization and Doppler data are available for each valve lesion; ΔP = mean transvalvular pressure gradient in mm Hg; Regurg = regurgitation (0 = absent; 1+ to 4+ severity); kHz × s = kilohertz seconds.

aortic regurgitation and mitral regurgitation). Of 23 patients who had disease of a single valve, 14 had combined aortic regurgitation and aortic stenosis, 3 had mitral stenosis and mitral regurgitation; only 6 patients had a single lesion involving a single valve. Fifteen patients had aortic stenosis with mean systolic pressure gradients of 10 to 103 mm Hg (mean 36); 5 had mitral stenosis with mean diastolic pressure gradients of 8 to 17 mm Hg (mean 13). Angiographic evidence of aortic regurgitation was present in 14; mitral regurgitation was proved in 10. Four patients had prosthetic aortic valves: 2 had aortic regurgitation and 2 had mild aortic stenosis.

High-quality Doppler recordings were obtained in 113 of 119 (95%) examination sites in which they were attempted. They were not available from 6 additional sites (5%) because of technical difficulty in obtaining adequate 2-dimensional echocardiographic images and/or adequate Doppler signals from the suprasternal notch (3) or the cardiac apex (3).

The data in Table I are grouped to illustrate the usefulness of the spectral envelope area in separating patients with a given valve lesion from those without it. There is complete separation of spectral envelope areas with no overlap between normal subjects and patients with aortic stenosis, mitral stenosis, and mitral regurgitation of native valves; overlap in spectral envelope area between a single patient with mild aortic regurgitation and the normal population is noted. For each examination site shown, there was statistically significant separation of mean values for spectral areas between normal and diseased patients ($p < 0.01$). Sample volume localization and registration were adequate to allow correct exclusion of aortic regurgitation in both patients with mitral stenosis and no aortic regurgitation; mitral stenosis was correctly excluded in all 8 patients with aortic regurgitation and no mitral stenosis.

Figures 4 through 7 illustrate Doppler audio spectral recordings characteristic of normal (left) and diseased (right) valves for each examination site. Doppler signals from the aortic valve outflow tract are narrow-band in the absence of a pressure gradient across the aortic valve; in the presence of aortic stenosis, spectral broadening is evident throughout systole (Fig. 4). In the absence of aortic regurgitation, Doppler records from the left ventricular outflow tract show narrow-band flow away from the transducer during systole; little flow is evident during diastole. In the presence of aortic regurgitation, broad-band spectral tracings are present throughout diastole (Fig. 5). Normal Doppler signals from the mitral valve outflow tract are characterized by a narrow-band spectral record that peaks early in diastole, decreases markedly in mid-diastole, and increases in late diastole with atrial contraction. In the presence of mitral stenosis, both mean and mid-diastolic Doppler frequencies are elevated; spectral broadening is evident throughout diastole (Fig. 6). Doppler signals from the mitral valve inflow tract are near zero during systole in normal subjects; when mitral regurgitation is present, broad-spectrum pansystolic recordings are noted (Fig. 7).

Of the 4 patients with prosthetic aortic valves, 2 had aortic regurgitation and 2 had no aortic regurgitation; all 4 were correctly classified using spectral envelope area ranges derived from native valves. Two prosthetic aortic valves had significant systolic transvalvular gradients (12 and 24 mm Hg); 1 had no gradient and another had a 3-mm Hg gradient. All 4 had systolic spectral envelope areas that were above values for normal native valves.

Discussion

The blood flow disturbance produced by a diseased heart valve is similar to that resulting from stenosis of a peripheral artery.[26–30,36] Within and immediately downstream from the stenotic valve, blood velocity is elevated; beyond and alongside the area of high velocity, blood flow is turbulent. Both turbulence and high-velocity flow may serve as markers of valvular heart disease. Doppler spectral broadening and high Doppler frequency shift would be the corresponding manifestations of disease.

The timing and location of the intracardiac flow disturbance produced by valve stenosis are similar to those of laminar flow through normal aortic and mitral valves. Thus, identification of valve stenosis depends on the detection of intracardiac flow disturbance at the

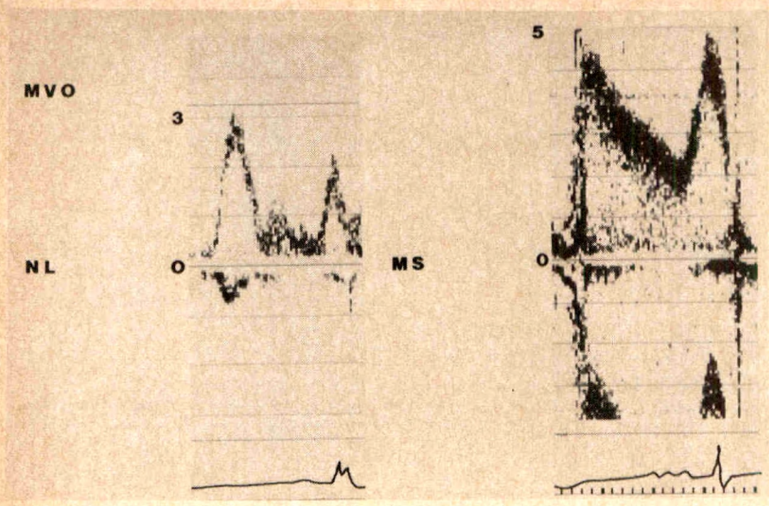

FIGURE 6. Doppler spectral records from the mitral valve outflow tract (MVO) of a normal subject (NL, **left panel**) and a patient with mitral stenosis (MS, **right panel**) are shown using the same format as in Figure 5. Note the diastolic spectral broadening and increased F_D in mitral stenosis.

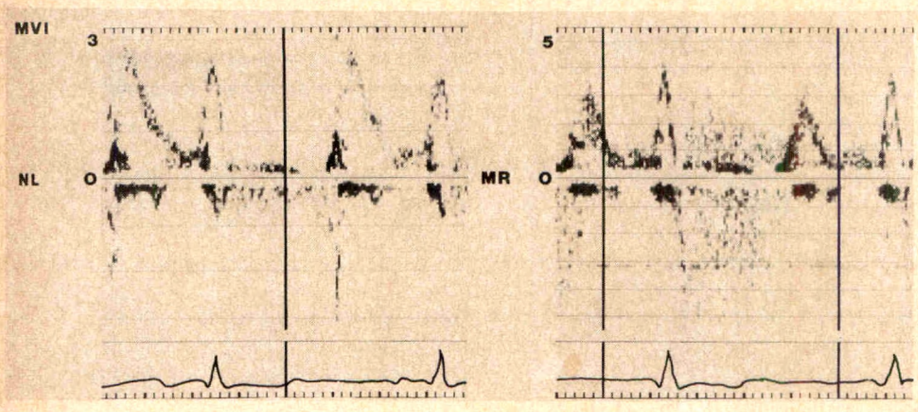

FIGURE 7. Doppler spectral records are illustrated from the mitral valve inflow tract (MVI) on the left atrial side of the mitral leaflets of a normal subject (NL, **left panel**) and a patient with mitral regurgitation (MR, **right panel**) using the same format as in Figure 5. Note the pansystolic spectral broadening in mitral regurgitation.

same time and location that normal flow would be anticipated. By contrast, valve regurgitation may be detected by finding abnormal location, direction, or timing of blood flow. Diastolic flow disturbance just below the aortic valve leaflets signifies aortic regurgitation and reflects the flow disturbance "upstream" from the regurgitant defect in the aortic valve cusp. Similarly, abnormal systolic flow induced by the defect in the mitral valve is detected on the left atrial side of the mitral leaflets.

If detection of extremely high-velocity flow is the diagnostic approach taken to detect valvular disease, continuous wave Doppler or very high pulse-repetition frequency pulsed Doppler instrumentation must be employed to avoid aliasing. Continuous wave Doppler has been useful in detecting aortic stenosis[37–39] as well as other left-sided valvular lesions.[40–42] Unfortunately, continuous-wave Doppler samples velocities along the entire ultrasound beam, not just at a selectable location. In addition, combined 2-dimensional cardiac imaging and continuous wave Doppler are not possible. Both problems may lead to ambiguity as to the exact source of the flow disturbance. Confusion would be anticipated in separating mitral stenosis from aortic regurgitation as the cause of diastolic flow disturbance in the left ventricular outflow tract. The greatest difficulty is anticipated when both lesions are present or when 1 or both are severe.

When detection of turbulence manifest by spectral broadening is used as the diagnostic indicator of disease, range-gating and registration of the intracardiac position of the sample volume are possible because Duplex pulsed-Doppler systems may be used. The importance of range-gating and accurate sample volume registration is illustrated by our ability to differentiate those patients in whom diastolic turbulence in left ventricular outflow tract was due to mitral stenosis versus aortic regurgitation. The technique involves noting changes in the severity of turbulence as the sample volume is moved from just below the aortic valve to the mitral valve outflow tract. In the presence of aortic regurgitation, the turbulence is most severe just below the aortic valve in the left ventricular outflow tract; in mitral stenosis, the turbulence is most evident near the mitral orifice. In our patient population both patients with mitral stenosis and no aortic regurgitation, all 8 patients with aortic regurgitation and no mitral stenosis, and both patients who had aortic regurgitation and mitral stenosis were correctly identified. No false-positive results were noted.

Previous studies have shown pulsed Doppler echocardiography to be reasonably accurate in detecting

mitral and aortic valve disease. Unfortunately, the equipment used in each of these previous reports required advanced operator skills to (1) interpret the Doppler audio signals used to indicate disease, (2) avoid artifacts due to improper gain settings on the representation of the spectral analysis, and (3) avoid inaccuracies in sample volume position inherent in M-mode visualization of cardiac anatomy.[14–25,31–34] Our study demonstrates the high degree of accuracy (specificity 100%; sensitivity 97%) possible when 2-dimensional echocardiographic registration of sample volume position and spectral analysis are combined; extensive training in audio recognition of abnormal Doppler signals is no longer required.

Quantification of the severity of aortic and mitral stenosis has been demonstrated with both continuous wave and pulsed-Doppler techniques. Using continuous wave Doppler, Hatle and others[38–42] found an excellent correlation between the severity of the pressure gradient across the mitral and aortic valves and the peak velocity detected. Spectral variables that reflect timing and severity of turbulence may be extracted from pulsed-Doppler signals; they correlate equally well with the severity of aortic stenosis.[43] Measurement of the volume distribution of flow disturbance, using pulsed-Doppler techniques, has been useful in determining the severity of mitral[25] and aortic[44] regurgitation. Because the emphasis of the study was on the precise definition of specific valvular pathology in adults with multiple valve disease and prosthetic valves, such complex data acquistion and signal processing techniques useful in quantifying severity were not employed.

Our data demonstrate a simple, highly accurate method of using currently available transcutaneous pulsed Doppler with spectral analysis and accurate location of sample volume position to detect or exclude the presence of aortic and mitral regurgitation and stenosis in adult patients. Detection depends on careful localization and timing of regions of turbulence within the heart. The area of the Doppler spectral envelope appears to be a useful indicator of turbulence and allows differentiation of diseased from normal valves. Correct identification of the site and type of valvular lesion remains accurate, even in the presence of multiple lesions. Preliminary data also suggest the usefulness of the technique in identifying aortic regurgitation in prosthetic aortic valves.

Long-Term Results of Tricuspid Valve Replacement And the Problem of Prosthetic Valve Thrombosis

CHARLES W. THORBURN, MRCP, FRACP, JOHN J. MORGAN, FRACP, MARK X. SHANAHAN, FRACS, and VICTOR P. CHANG, FRCS, FRACS

Observations in 71 patients having tricuspid valve replacement over a 14-year period are described. The operative mortality rate was 10% and the actuarial survival rate was 73% at 5 years and 47% at 10 years. Survival was unaffected by the number of valves replaced or the type used (27 Starr-Edwards, 32 Björk-Shiley, 8 Lillehei-Kaster, and 4 porcine xenografts). Complications were common: 3 deaths were related to anticoagulation and 1 was due to a systemic embolus. Six patients required permanent pacing.

There was a very high incidence of thrombosis of the prosthetic tricuspid valve. Twenty percent of the tilting disc valves thrombosed, compared with 4% of the Starr-Edwards valves ($p < 0.05$). Symptoms of thrombosis were usually insidious, and its diagnosis was often delayed. There was a continuing risk of this complication, and presentation occurred up to 12 years after the original operation. Thrombolytic therapy with streptokinase was successful in 1 of 2 patients. Replacement of the thrombosed prosthetic valves was carried out without mortality in 8 patients.

Surgical correction of tricuspid regurgitation is usually considered in patients having mitral valve replacement for severe congestive cardiac failure. In most patients tricuspid regurgitation is secondary to dilatation of the tricuspid anulus and would be expected to resolve after successful mitral valve replacement.[1] In our experience, however, the tricuspid regurgitation did not resolve and in some patients became more severe. In 1966, our policy was to repair the tricuspid valve in patients shown at cardiac catheterization to have significant tricuspid regurgitation. Early experience with anuloplasty was disappointing, so most patients had tricuspid valve replacement. This report describes our experience with 71 patients who underwent tricuspid valve replacement.

Methods

Between July 1966 and January 1980, 71 patients underwent tricuspid valve replacement. The operations consisted of 1 single valve, 33 double valve, and 37 triple valve replacements. Eight operations were necessary for thrombosed tricuspid valves. Four types of valves were used in the tricuspid position: 27 Starr-Edwards, 32 Björk-Shiley, 8 Lillehei-Kaster, and 4 porcine xenografts. The hospital records of the patients were analyzed for preoperative clinical status (New York Heart Association classification), cardiac catheterization data, and data relative to the immediate and late postoperative course. Follow-up study of those patients not attending the hospital was achieved by written and telephoned questionnaire of the patient's own physician. Particular emphasis was placed on the incidence of embolization, bleeding, anticoagulant control, and valve thrombosis. In this way, it was possible to obtain the total mortality figure. Follow-up of all living patients with respect to clinical status was also achieved. In some patients who had died, data on their antemortem clinical status were incomplete. Actuarial survival curves were constructed according to the method described by Cutler and Ederer,[2] and the statistical analysis was carried out using the method of Oleinick and Mantel[3] for incidence density data. A provisional recommendation for tricuspid valve replacement was made on the basis of clinical findings, cardiac catheterization data, and right ventricular angiogram. Tricuspid regurgitation was confirmed at operation. Occasionally, tricuspid regurgitation was not considered significant until difficulty was encountered in maintaining an adequate circulation after replacement of the other valves. Until October 1977, operations were carried out under cardiopulmonary bypass with moderate hypothermia to 30°C together with aortic cross-clamping and coronary perfusion during replacement of the aortic and mitral valves. Since October 1977, cold cardioplegia and topical hypothermia have been used without coronary perfusion. Postoperative anticoagulation therapy with warfarin sodium is started on the second post-

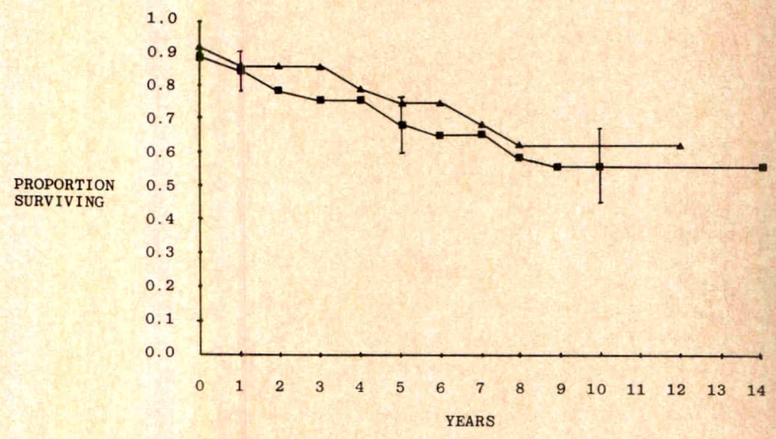

FIGURE 2. Actuarial survival curve for patients undergoing double (n = 33) and triple (n = 37) valve replacements, demonstrating no difference between the 2 groups. **Triangles** = double valve replacement; **squares** = triple valve replacement.

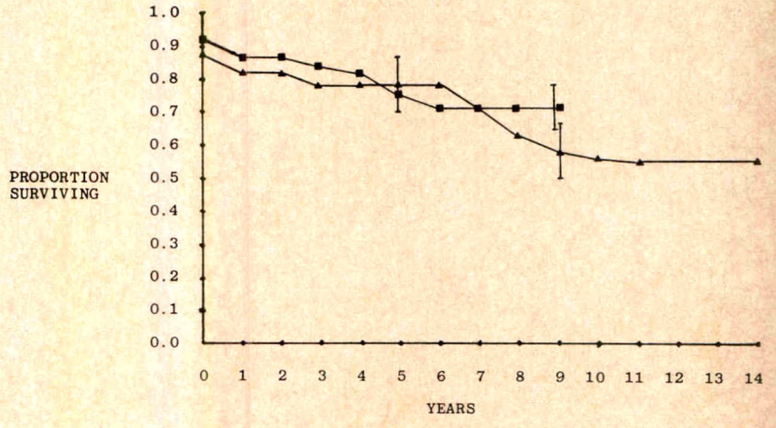

FIGURE 3. Actuarial survival curve for patients having tricuspid valve replacement with Starr-Edwards (n = 27) valves 6120 and tilting disc (n = 40) valves (Björk-Shiley and Lillehei-Kaster), demonstrating no difference between the 2 groups. **Triangles** = Starr-Edwards valves; **squares** = tilting disc valves.

operative day unless contraindicated. All patients are on permanent anticoagulant therapy. The prothrombin time is estimated monthly and is maintained at 2 to 3 times the control time.

Results

The operative mortality rate was 10%, with 7 hospital deaths, 4 of which were due to persistent cardiogenic shock. One death was due to undiagnosed asymmetric septal hypertrophy, resulting in malfunction of the Starr-Edwards mitral prosthesis because of disproportion. One death was due to pericardial tamponade and 1 death to pulmonary embolus after intractable postoperative hematemesis.

Actuarial survival curves for the 71 patients are shown in Figure 1. Survival is 86% at 1 year, 73% at 5 years, and 47% at 10 years. There was no difference between double and triple valve replacements in terms of survival (Fig. 2), nor was there any difference in survival between patients with Starr-Edwards valves and those with tilting disc valves (Fig. 3). This finding was unexpected, as the Starr-Edwards valve was used

TABLE I Cardiac Index (liters/min/m²) Pulmonary Arterial Wedge Pressure (mm Hg) and Left Ventricular End-Diastolic Pressure (mm Hg) in Different Patient Survival Groups (Mean Values ± Standard Deviation)

	n	Cardiac Index (liters/min/m²)	PAW	LVED
Operative deaths	7	2.0 ± 0.4	21 ± 7	9 ± 5
Deaths in first year	4	2.5 ± 0.9	14 ± 9	9 ± 4
First-year survivors	53	2.1 ± 0.6	19 ± 7	11 ± 5

Xenograft (8 reoperations)	12	0	0	12	0
All tilting disc	40	8	20	199	4

up to 1971 and the tilting valve thereafter. There was no relation between operative mortality and preoperative cardiac catheterization data (Table I), nor between operative mortality and preoperative New York Heart Association classification. Morbidity (Table II) demonstrates the continued risk associated with multiple prosthetic valve replacement and anticoagulation. Emboli were defined as major when sequelae were permanent and minor when they were not. Hemorrhage was considered major when the patient required admission to the hospital.

Prosthetic valve thrombosis: This complication was confined to the tricuspid valve and was common with the Lillehei-Kaster and Björk-Shiley tilting disc valves (Table III). One Starr-Edwards valve thrombosed in a patient with Ebstein's anomaly who had an extremely dilated and poorly contracting right ventricle. To date, no cases of thrombosis of porcine xenografts have occurred during their shorter follow-up period. The difference between the incidence of late thrombosis with tilting disc and Starr-Edwards valves is significant ($p < 0.05$). Brief clinical details of the affected patients are given in Table IV. It can be seen that there is a continuing risk of this complication with presentation as late as 11 years after operation. In contrast to the acute presentation of thrombosis of a mitral valve prosthesis, the onset of symptoms with the tricuspid valve was usually insidious. Edema was noted in 8 patients and breathlessness in 5. The duration of symptoms ranged from 2 weeks to 1 year, with only 2 patients having symptoms for <1 month. Patient 2 had no symptoms referable to the tricuspid valve thrombosis, which was only detected during routine clinical examination. Physical examination revealed a markedly elevated jugular venous pressure in all 9 patients, reduced valve sounds in 5, and tricuspid diastolic murmurs in 8. The patient in whom a diastolic murmur was not detected was extremely obese.

Cardiac catheterization (Table IV) demonstrated a high right atrial pressure in all patients. The mean tricuspid valve gradient ranged from 5 to 18 mm Hg. Right atrial angiography invariably showed slow atrial

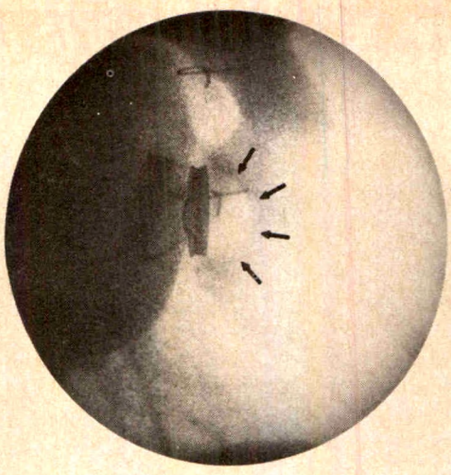

FIGURE 4, left. Right atrial angiogram in Patient 4. The large filling defect (**arrow**) is due to a thrombus on the tricuspid valve.

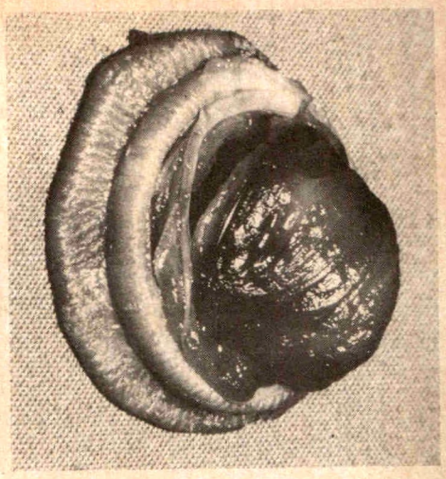

FIGURE 5, right. Operative specimen corresponding to the angiographic findings in Figure 4.

emptying, but demonstrated thrombus in only 1 patient (Fig. 4). The operative findings in this patient are shown in Figure 5. Streptokinase therapy was used in 2 patients, both of whom had symptoms suggesting tricuspid valve thrombosis for more than 6 months. The patient treated successfully had return of valve sounds after 24 hours of treatment. Right-sided pressure recordings before and after treatment are shown in Figure 6. In the second patient, thrombolytic therapy failed. At operation the valve was found to be obstructed by the septal leaflet of the native tricuspid valve. No mortality was associated with reoperation carried out in 8 patients.

Discussion

The operative mortality of 10% compares favorably with other reported mortalities of 11 to 14%.[4–9] In contrast to findings in other reports,[4,7,8] no relation appeared to exist between the preoperative New York Heart Association classification and early or late mortality.

Although the continuing morbidity of patients with prosthetic valves is well known, the incidence of thrombosis of these valves in the tricuspid position is surprisingly high. The tricuspid valve seems to be particularly vulnerable to this complication, which can occur many years after the original operation.[10–15] Poor anticoagulant control was perhaps a factor in 4 patients. Lower pressures on the right side of the heart with slower blood flow across the tricuspid valve must be important factors. In patient 8 there was an anatomic reason in that the residual septal leaflet interfered with the opening of the disc (Fig. 7). The leaflet was initially mobile, but gradually fibrosed into a band, restricting disc movement.

The significantly higher incidence of tricuspid valve thrombosis with the tilting disc valves compared with the Starr-Edwards valves has not previously been reported. It could be expected from experience with these valves in the mitral position. The situation with tricuspid valve thrombosis is much less dramatic, because a sudden large increase in right atrial pressure merely results in peripheral edema. All but 1 patient had an insidious presentation, usually with gradually increasing edema and dyspnea on exertion.

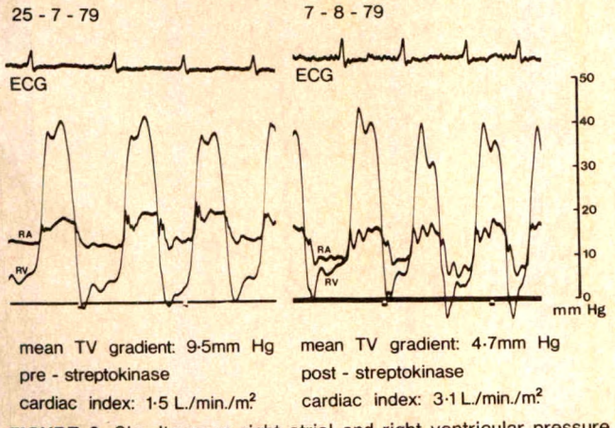

FIGURE 6. Simultaneous right atrial and right ventricular pressure tracings in patient 9, demonstrating marked reduction in tricuspid valve gradient and increase in cardiac output after streptokinase therapy. ECG = electrocardiogram; TV = tricuspid valve.

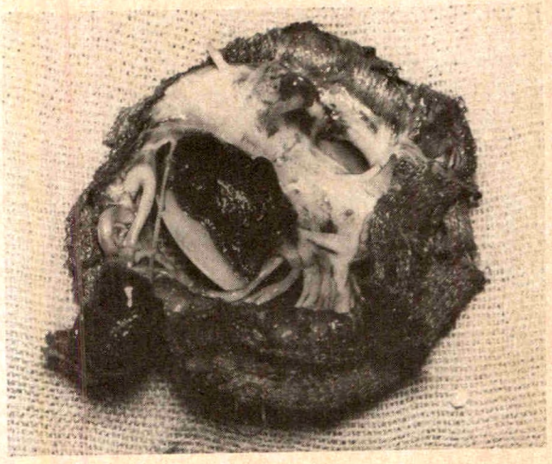

FIGURE 7. Operative specimen from patient 8. The septal leaflet of the native tricuspid valve interferes with the opening of the prosthetic valve.

Physical examination demonstrated significantly increased jugular venous pressure in all cases. All but 1 patient had a diastolic murmur that was high pitched in patients with a large gradient. The intensity of valve sounds was reduced in 5 patients.

Tricuspid valve thrombosis must be distinguished from thrombosis of a left-sided valve which is usually a much more dramatic event with marked left-sided failure. Because of their insidious presentation, with dyspnea and edema, many of the patients were thought to have myocardial failure. The distinction was made by the lack of pulmonary congestion on chest X-ray and by the demonstration of good left ventricular function on echocardiography. In our experience, the echocardiogram has otherwise proved to be disappointing in the diagnosis of thrombosed valves. The diagnosis of thrombosis was confirmed at cardiac catheterization by the demonstration of a significant gradient across the tricuspid valve in 8 patients (Table IV). In only 1 patient was a thrombus visualized at angiography (Fig. 5 and 6).

With the possibility of using streptokinase therapy,[16,17] the diagnosis must be made as early as possible so that treatment can be initiated before organization and fibrosis of the thrombus has occurred. The patients reported on in the literature have all had recent thrombosis, although our successfully treated patient had a history suggestive of thrombosis for 9 months before treatment.

Although Braunwald et al[1] reported that functional tricuspid regurgitation usually resolved after successful surgery, subsequent experience does not support this finding. Increasing use was made initially of tricuspid valve replacement and subsequently of tricuspid valve anuloplasty and valvuloplasty. Although initially there was some disagreement as to which of these techniques gives the best results, there is now wide acceptance of the conservative management of tricuspid regurgitation.[18,19] At our institution, it is now rare to replace the tricuspid valve, and the most common indication since 1976 has been thrombosis of a prosthetic valve.

Porcine xenograft is now the valve of choice in tricuspid valve replacement. However, thrombosis has been reported in the immediate postoperative period in patients with very low cardiac output,[20] and Horowitz[21] demonstrated that the porcine valve opens poorly under low pressure. In our limited follow-up, there have been no instances of thrombosis. The Björk-Shiley and Lillehei-Kaster valves must be considered unsuited to the tricuspid position because of their tendency to thrombotic obstruction. The Starr-Edwards valve had only a low incidence of thrombosis, although there have been several reports in the literature.[7,8,10–13] In most of these reported cases, there was an anatomic cause for the thrombosis, usually a strut of the valve being embedded in the muscle of the right ventricle. In the mitral position, thrombosis of the Starr-Edwards valve is rare. Thromboembolism is the more common problem, and on the right side of the heart infrequent small emboli are not likely to be a problem in the pulmonary circulation. Our data indicate that Starr-Edwards valve 6120 is a satisfactory valve for the tricuspid position, especially when the patient is young and requires anticoagulant therapy.

Conclusion: From this study the Björk-Shiley and Lillehei-Kaster tilting disc valves prove to have an unacceptably high rate of thrombosis in the tricuspid position. Starr-Edwards valve 6120 and the porcine xenograft appear to be satisfactory. The clinical picture of prosthetic tricuspid valve thrombosis has been described as an insidious one, with the diagnosis often being delayed. Treatment with streptokinase may be successful. Reoperation can be undertaken with a low risk.

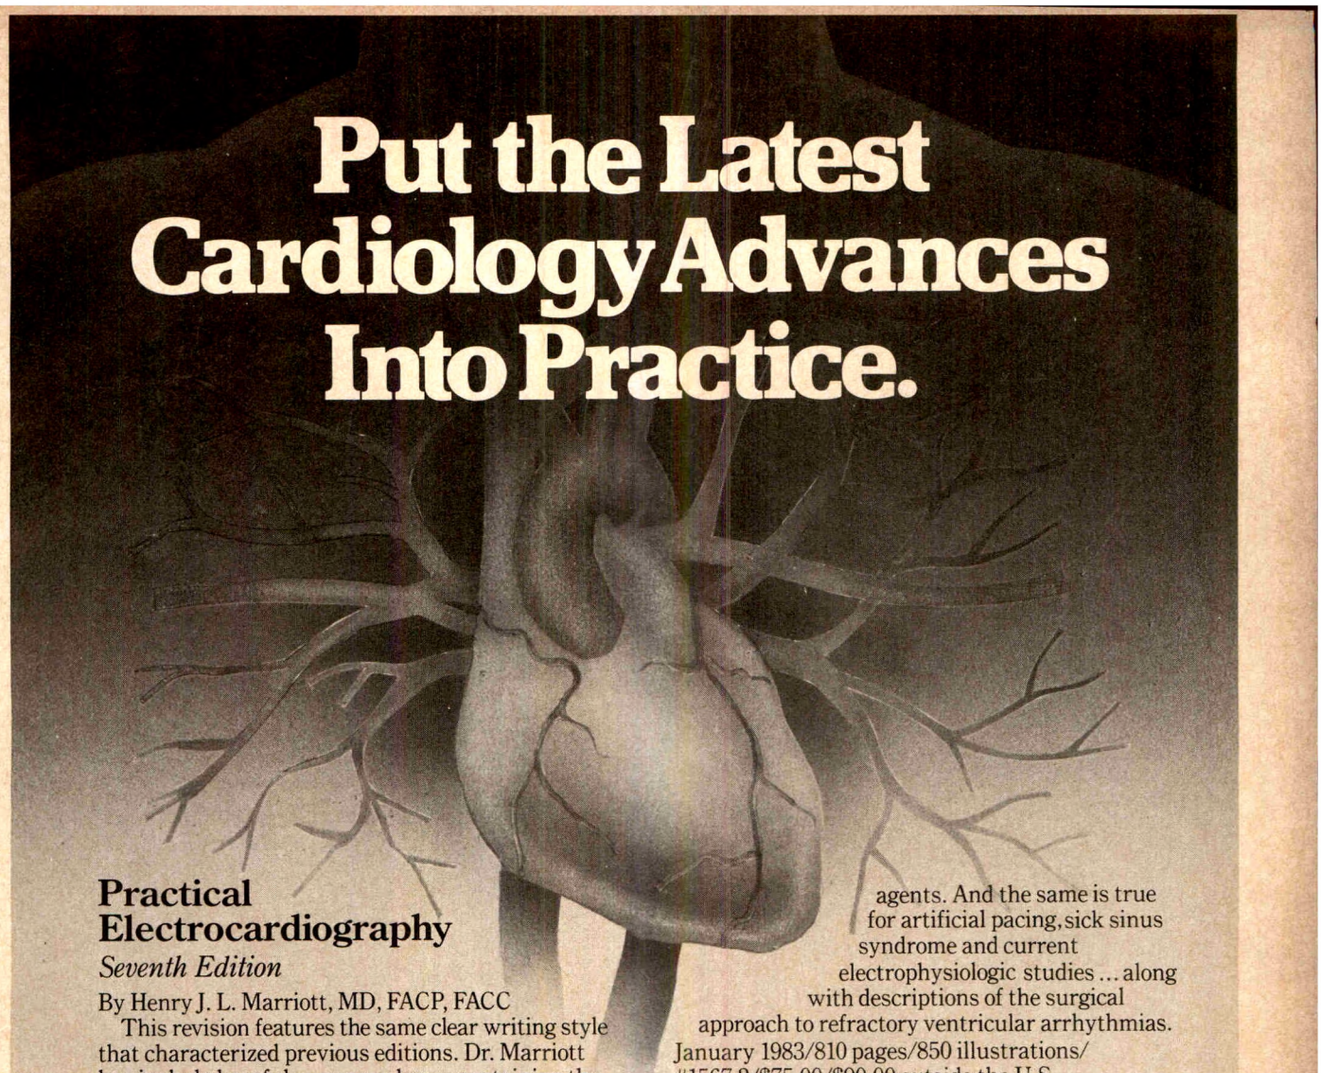
Put the Latest Cardiology Advances Into Practice.



Practical Electrocardiography

Seventh Edition

By Henry J. L. Marriott, MD, FACP, FACC

This revision features the same clear writing style that characterized previous editions. Dr. Marriott has included useful summary boxes containing the salient diagnostic features of many of the subjects covered. Among the changes you'll find:

- Coronary insufficiency and related matters have a greatly expanded section
- 156 new illustrations, 15 new review tracings have been added
- Extensive revisions to chapters on bundle-branch block and aberrant ventricular conduction including effective treatment modalities
- Greater detail on the systematic approach to diagnosis of arrhythmia, extrasystols, atrial flutter, and atrial fibrillation.

If you're interested in using **Practical Electrocardiography** as a text, write to Pamela Caras in the Marketing Department for an examination copy.
April 1983/496 pages/479 illustrations/#5574-7/ $18.95/$19.95 outside the U.S.

Principles of Cardiac Arrhythmias

Third Edition

By Edward K. Chung, MD, FACP, FACC

Crystal-clear reproductions of ECG tracings show every known cardiac arrhythmia in the human heart. You get detailed descriptions of all anti-arrhythmia drugs including investigational agents. And the same is true for artificial pacing, sick sinus syndrome and current electrophysiologic studies ... along with descriptions of the surgical approach to refractory ventricular arrhythmias.
January 1983/810 pages/850 illustrations/ #1567-2/$75.00/$90.00 outside the U.S.

Moss' Heart Disease in Infants, Children, and Adolescents

Third Edition

Edited by Forrest H. Adams, MD and George C. Emmanouilides, MD, with 77 contributors

This standard reference and clinical guide has been revised to include new contributors and new topics: prostaglandins in the newborn, nuclear cardiology, and new treatments for pulmonary hypertension. Nearly 80 authorities from 35 major medical centers describe advances and changes in their areas since the last edition was published.

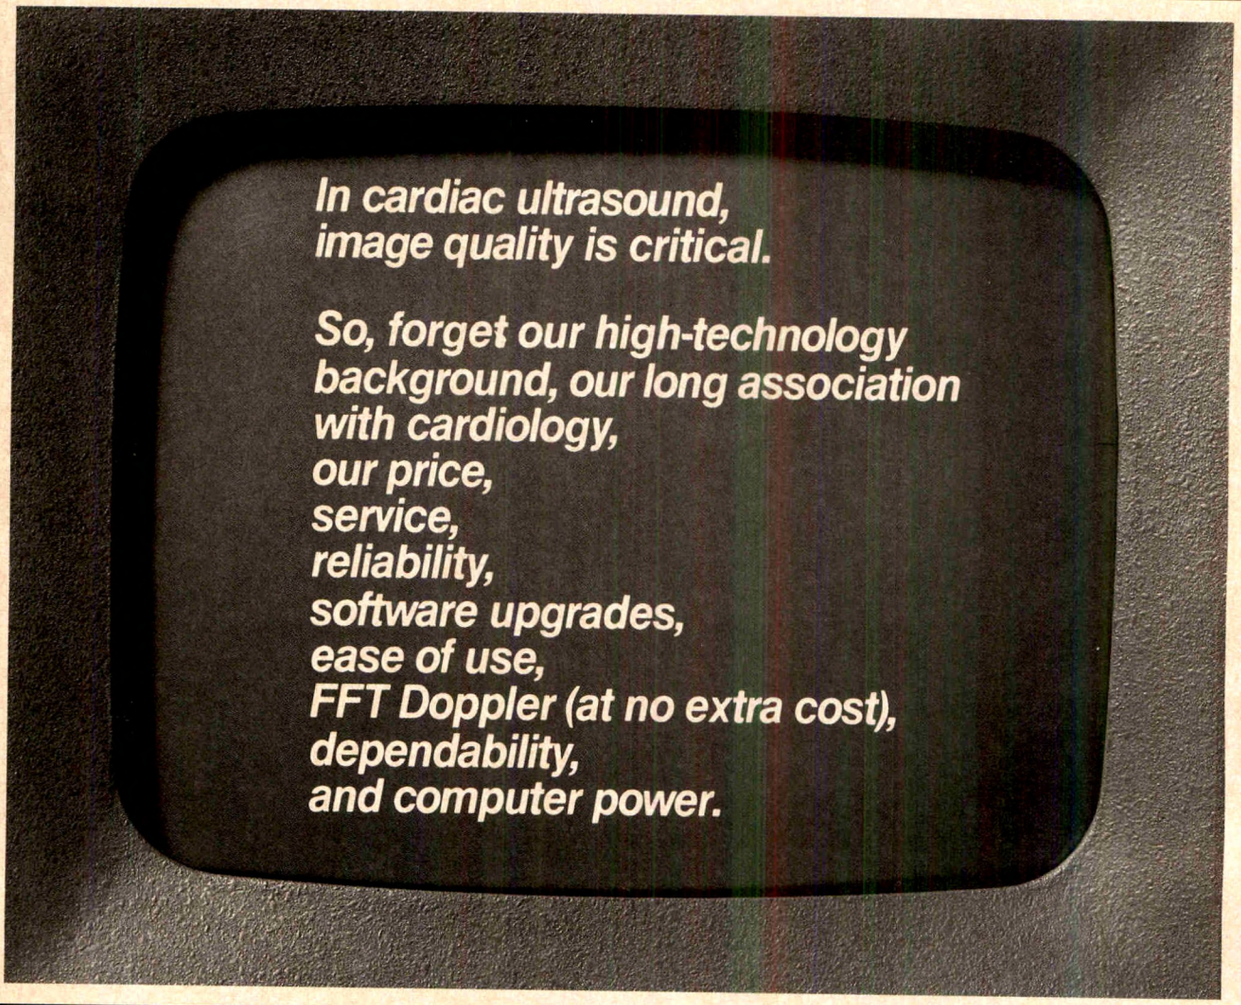
Ultra



Instead, do just one thing: Compare our image for yourself...

E FOR M / Honeywell

Imager

The Electronics for Medicine/ Honeywell Ultra Imager gives you so many features for such a reasonable price, you could choose it for this reason alone.

But we don't want you to.

Instead, what we want you to do is call us, along with the manufacturer of any other comparable cardiac ultrasound system, for a demonstration. You can even let them bring along their best sonographer.

Then, compare the quality of the two images side-by-side.

What will you find?

We're convinced that once you've seen the difference for yourself, you'll find that in this comparison, there is just no comparison.

The E for M/Honeywell Ultra Imager.

We don't just *claim* to have better image quality.

We're willing to prove it.

For more details or a demonstration, call, toll-free, (800) 328-5111 extension 174. In Minnesota, call collect (612) 870-2682, extension 174. Or write our Customer Communications Center, P.O. Box 16525, Denver, Colorado 80216.

Nitroglycerin
effective for
24 hours.

Overcomes the limitations of sublingual, oral and topical nitrates.

Sublingual—A short duration of action (approximately 12 minutes) limits sublingual nitroglycerin use in an acute attack or prophylaxis in an anticipated stress situation.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System provides protection continuously for 24 hours, even during an unanticipated stress situation.

Oral—Protection is unreliable with oral nitrates, since the drug is metabolized on the first pass through the liver.

Nitro-Dur is absorbed into the venous system through the skin, thereby avoiding first-pass inactivation.

Topical—Nitroglycerin ointments have a duration of action that ranges from 4 to 8 hours.

But dosing with an ointment is difficult, messy, imprecise and subject to patient error. Dose-to-dose variations are unavoidable.

Nitro-Dur is the first transdermal nitroglycerin to offer precision in dosing, elegance and patient security. In contrast to other nitrates, Nitro-Dur is also easy to apply and effective for 24 hours.

Nitroglycerin therapy is contraindicated in patients with increased intraocular pressure. Symptoms of hypotension may be due to overdosage. If hypotension occurs, the dosage should be reduced. In terminating treatment, the dosage must be gradually reduced over a 4 to 6 week period.

A unique method of delivering nitroglycerin.

Nitro-Dur contains nitroglycerin in a gel-like matrix attached to an adhesive bandage. It is available in four dosage strengths: 5, 10, 15 and 20 cm^2, permitting titration in 5 cm^2 increments. From these sizes, the approximate rated release in vivo per 24 hours is 2.5, 5, 7.5 and 10 mg of nitroglycerin, respectively. Nitro-Dur has greater dosage flexibility than any other transdermal nitroglycerin.

When Nitro-Dur is applied to the skin surface, the drug diffuses through the skin at a constant rate. The process is continuous, providing a steady, predictable flow of nitroglycerin from the matrix to the skin and finally into the blood.

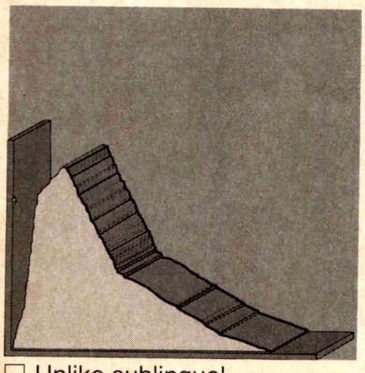
In bioavailability studies,* transdermal absorption of nitroglycerin from the Nitro-Dur matrix achieved steady-state venous plasma levels and maintained these levels for 24 hours. For each square centimeter of matrix, Nitro-Dur delivers approximately 0.5 mg of nitroglycerin through the rate-limiting barrier of the skin, the stratum

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

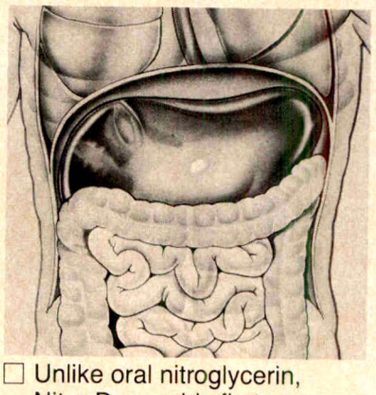
Please see next page for a summary of prescribing information.

*Data on file, Key Pharmaceuticals, Inc.

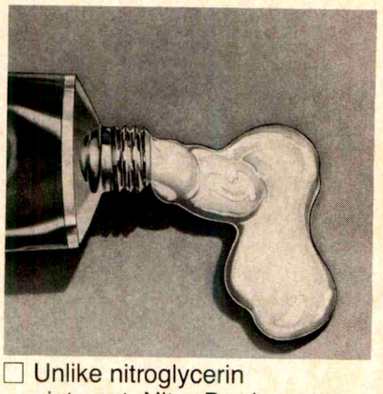
Nitroglycerin effective for 24 hours.



☐ Unlike sublingual nitroglycerin, Nitro-Dur™ (nitroglycerin) provides protection for 24 hours.



☐ Unlike oral nitroglycerin, Nitro-Dur avoids first-pass inactivation.



☐ Unlike nitroglycerin ointment, Nitro-Dur is easy to apply and provides precise, reproducible dosing.

Easy and convenient to apply.

1. Apply Nitro-Dur to the upper arm or a hair-free portion of the chest. The area selected must be clean and dry.

2. Allow Nitro-Dur to remain in place for 24 hours. Showering is permitted while wearing the bandage.

Simple to titrate.

Titration should be in increments of 5 cm^2. Relief of anginal symptoms and/or reduction of sublingual tablet usage should be indicators in determining a patient's optimal therapeutic level. With Nitro-Dur, there is no need to titrate to headache.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm^2, 10cm^2, 15cm^2 and 20cm^2, containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm^2/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm^2, 10cm^2, 15cm^2 and 20cm^2, is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

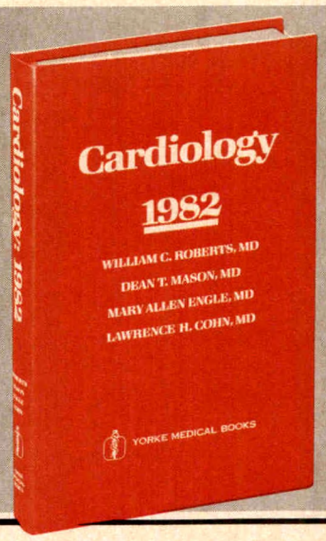
CARDIOLOGY: 1982

The Second Issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

written by:

- **William C. Roberts, M.D.**
  Chief, Pathology Branch/National Heart, Lung & Blood Institute/National Institutes of Health/and Clinical Professor of Pathology & Medicine (Cardiology)/Georgetown University School of Medicine, Washington, D.C.
- **Dean T. Mason, M.D.**
  Professor of Medicine and Physiology, and Chief of Cardiovascular Medicine, University of California, Davis School of Medicine and University Medical Center, Davis and Sacramento, California
- **Mary Allen Engle, M.D.**
  Stavros S. Niarchos Professor of Pediatric Cardiology/Director of Pediatric Cardiology/The New York Hospital-Cornell University Medical College, New York
- **Lawrence H. Cohn, M.D.**
  Professor of Surgery/Harvard Medical School/Department of Surgery/Division of Thoracic & Cardiac Surgery/Brigham & Women's Hospital, Boston

ISBN 0-914316-27-3 approx. 500 pp., illus., April 1982, $45.00 ISSN 0275-0066



What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

CARDIOLOGY: 1982 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well-established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and original tables condenses valuable information into instantly understandable knowledge.

Reviews of the first edition

"...recommend...to any reader interested in the literature of cardiology."
Irwin R. Callen, M.D.
JAMA, November, 1981

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended."
Philip Reichert, M.D.
New York State Journal of Medicine, September, 1981

"This is an excellent book, very well organized and written...should be on the shelf of the library, cardiologist, and internist."
COL. Robert B. Franklin, MC, USA
Military Medicine, November, 1981

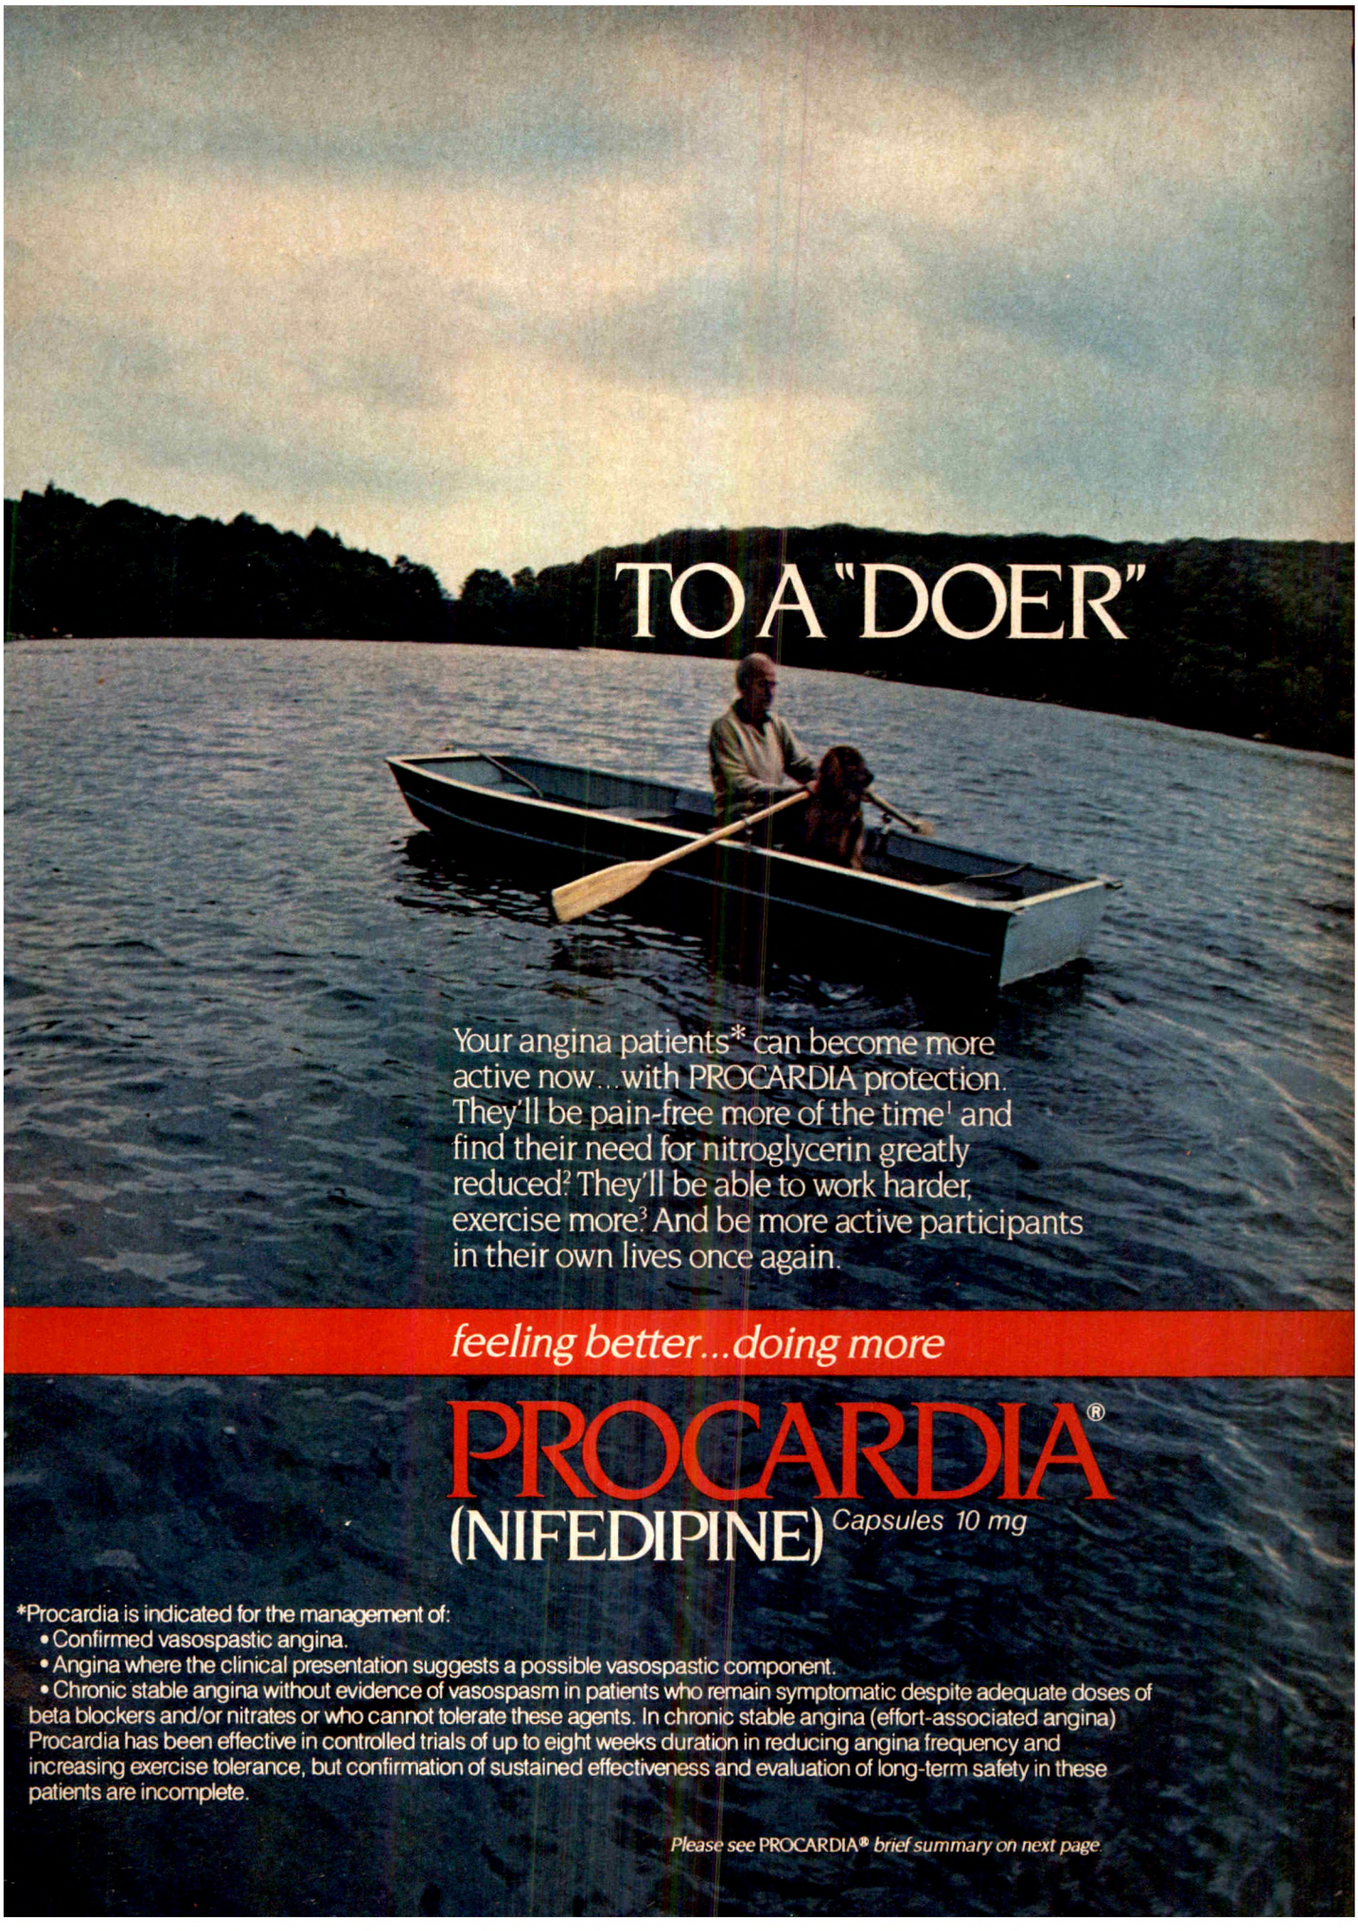
FROM A "WATCHER"...



Your angina patients* can become more active now...with PROCARDIA protection. They'll be pain-free more of the time[1] and find their need for nitroglycerin greatly reduced.[2] They'll be able to work harder, exercise more.[3] And be more active participants in their own lives once again.

feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA® *brief summary on next page.*

feeling better...doing more

PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA® CAPSULES For Oral Use
(nifedipine)

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out.

Increased Angina: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

Symptomatic Sick Sinus Syndrome in Children and Adolescents as the Only Manifestation of Cardiac Abnormality or Associated With Unoperated Congenital Heart Disease

STANLEY D. BEDER, MD, PAUL C. GILLETTE, MD, ARTHUR GARSON, Jr., MD, CO-BURN J. PORTER, MD, and DAN G. McNAMARA, MD

Sick sinus syndrome (SSS) occurs infrequently in children who have not undergone cardiac surgery. The symptoms, electrocardiograms, and electrophysiologic data in 11 patients aged 2 to 17 years who had nonsurgical SSS were reviewed. Syncope occurred in 5 patients and sinus bradycardia in 9. Sinus nodal recovery times were prolonged in 6 patients. The atrial effective refractory period was prolonged in 2 patients and the atrioventricular nodal functional or the effective refractory period, or both, was prolonged in 5 patients. Because patients with nonsurgical SSS may have abnormalities not only of the sinus node but also of the atrium and the atrioventricular node, it is recommended that patients with symptomatic SSS be evaluated by electrophysiologic study. The proper choice of antiarrhythmic drug therapy or permanent pacing procedure depends on a complete analysis of the cardiac conduction system.

Sick sinus syndrome (SSS) after corrective surgery for congenital heart disease has been reported by numerous investigators.[1–5] SSS has been reported less frequently in pediatric patients with either unoperated congenital heart disease[6,7] or with structurally normal hearts.[8–11] This investigation reviews our experience with nonsurgical SSS.

Methods

We reviewed the charts of our patients diagnosed as having SSS between 1972 and 1981. Patients who had SSS after open or closed cardiac surgery were excluded. We did, however, include 1 patient who had SSS after repair of a vascular ring. Eleven patients, aged 2 to 17 years, had nonsurgical SSS. Of these 11 patients, 8 had structurally normal hearts and 3 had either congenital or acquired heart disease.

The symptoms, resting electrocardiograms, and ambulatory electrocardiograms of each patient were reviewed. After noninvasive evaluation, each patient underwent invasive electrophysiologic study according to techniques previously described for our laboratory.[12] All cardiac medications were discontinued 24 hours before electrophysiologic study. The patients were sedated with meperidine, 2 mg/kg, and promethazine, 0.5 mg/kg, 30 minutes before study. Since this investigation spanned 9 years, our protocol has varied somewhat and not all measurements were obtained for each patient. During electrophysiologic study, we recorded the maximal corrected sinus nodal recovery time, total sinoatrial conduction time, atrial muscle effective refractory period, intraatrial conduction time (high right atrium to low septal right atrium), anterograde atrioventricular nodal functional refractory period, anterograde atrioventricular nodal effective refractory period, atrioventricular nodal conduction time (A-H), His-Purkinje conduction time (H-V), the atrial pacing cycle length at which atrioventricular nodal Wenckebach was first observed, and whether or not supraventricular tachycardia or atrial flutter or fibrillation was inducible during the study. Definitions of these refractory periods, as well as normal values, were previously reported.[12–15]

Results

Clinical features: Eight of our 11 patients had structurally normal hearts. Three had either congenital or acquired heart disease. The associated cardiac diseases were a vascular ring and small ventricular septal defect in 1 patient, an absent left pulmonary artery in another patient, and cardiomyopathy in the third pa-

† Maximal junctional recovery time.
‡ Low right atrial rhythm.
§ Presence of both Kent and James fibers in this patient prevented these measurements.

A_1-A_1 = sinus cycle length; A-H = low septal right atrium to His (atrioventricular nodal) conduction time; AM ERP = atrial muscle effective refractory period; Ante AVN ERP = anterograde atrioventricular nodal effective refractory period; Ante AVN FRP = anterograde atrioventricular nodal functional refractory period; HRA-LSRA = high right atrium to low septal right atrium (intraatrial) conduction time; H-V = His to ventricle (His-Purkinje) conduction time; JR = junctional rhythm interfered with these measurements; Max CSNRT = maximal corrected sinus nodal recovery time; NI = normal; NP = not part of our protocol at time of patient's study; S_1-S_1 = paced atrial cycle length; SACT = total sinoatrial nodal conduction time; SVT = supraventricular tachycardia.

tient. The latter patient with cardiomyopathy is the only 1 of our 11 patients who had a significant intrinsic myocardial abnormality.

The age at presentation ranged from 2 to 17 years. Nine of the 11 patients were male. Symptoms included syncope or near-syncope (5 patients), chest pain (3), palpitations (5), dizziness (3), and pallor, tachypnea, and disorientation (1).

Electrocardiographic findings: The most frequent resting and ambulatory electrocardiographic finding was sinus bradycardia (9 patients). Three patients had sinus rates <40 beats/min, and 2 of these had a sinus rate of 30 beats/min. The next most common electrocardiographic finding was supraventricular tachycardia (5 patients). Sinus pauses of up to 3.2 seconds' duration were noted in 2 patients. Wolff-Parkinson-White Syndrome (1 patient), atrial flutter (1), junctional rhythm (1), premature junctional and atrial contractions (1), and atrioventricular dissociation (2) were also seen.

Electrophysiologic evaluation of sinus nodal function: During electrophysiologic study, we assessed sinus nodal function by measurement of the maximal corrected sinus nodal recovery time and total sinoatrial conduction time (Table I). The maximal corrected sinus nodal recovery time was measured in 9 of the 11 patients. The sinoatrial conduction time was measured in 6. Sinoatrial conduction time was not determined in some patients, either because they had incessant tachycardia (JP) or junctional rhythm (RG), or because the determination of sinoatrial conduction time was not yet part of our routine protocol (TP, SB, SE). The range of maximal corrected sinus nodal recovery times was 10 to 4,000 ms. Our upper limit of normal for corrected sinus nodal recovery time is 275 ms,[16] and 6 of 9 patients exceeded this value. Three of these patients had extremely long maximal corrected sinus nodal recovery times of 2,350, 2,440, and 4,000 ms. Our upper limit of normal for sinoatrial conduction time is 200 ms[16]; only 3 of 6 patients had prolonged sinoatrial conduction times.

Electrophysiologic evaluation of atrial muscle function: We assessed atrial muscle function during electrophysiologic study by measurement of the intraatrial conduction time and the atrial muscle effective refractory period (Table I). Intraatrial conduction time (high right atrium to low septal right atrium) was only slightly prolonged in 1 of 10 patients (50 ms, DA). The atrial muscle effective refractory period was only prolonged in 2 of 8 patients.

Electrophysiologic evaluation of atrioventricular nodal function: The resting atrioventricular nodal conduction time (A-H) was only slightly prolonged in 2 of 10 patients (140 ms, SB; and 150 ms, DA). The anterograde functional refractory period of the atrioventricular node was prolonged in 4 of 7 patients. The anterograde effective refractory period of the atrioventricular node was prolonged in 2 of 6 patients. Wenckebach developed in the atrioventricular node at atrial pacing cycle lengths of ≤300 ms in 3 of 8 patients and at atrial pacing lengths of ≥420 ms in 5 of 8 patients. In our laboratory, we consider Wenckebach cycle lengths ≤300 ms (≥200 beats/min) normal and ≥400 ms (≤150 beats/min) abnormal (unpublished data).

Induction of tachycardia: We were able to induce supraventricular tachycardia in 5 of 11 patients. During electrophysiologic study, the tachycardia was induced by programmed premature atrial or ventricular stimulation, or a combination of these. The mechanism of supraventricular tachycardia was atrioventricular nodal reentry in 2 of 5 patients and atrial muscle reentry in 1 of 5 patients. In 2 of 5 patients, both a James fiber and a concealed Kent bundle (1 left Kent, 1 right anterior Kent) were present. The Kent bundle participated in the tachycardia circuit in both of these patients as demonstrated by eccentric atrial activation sequence during supraventricular tachycardia and by elimination of tachycardia after surgical division of the Kent bundle. In 1 of these 5 patients, we were also able to reproducibly induce atrial fibrillation (JB).

Follow-up and treatment: Of our 11 patients, 4 were seen at a one-time consultation only. The follow-up period ranged from 1.5 to 11 years in the remaining 7 patients (mean 4 years). Eight of our 11 patients required implantation of a permanent pacemaker. An atrial demand pacemaker was implanted in 5 of 8 patients and a ventricular demand pacemaker was implanted in 3. Of the patients who received pacemakers, 6 of 8 required no medication after pacemaker implantation. All 3 patients who did not receive pacemakers have been receiving digoxin therapy.

Discussion

Numerous criteria have been used to define SSS. Some workers diagnose SSS only when there are both electrocardiographic findings and symptoms suggesting sinoatrial nodal dysfunction.[17] Others have suggested that the presence of surface electrocardiographic or invasive electrophysiologic findings consistent with abnormal sinus nodal function, whether or not symptoms are present, is sufficient for the diagnosis of SSS.[18,16] In our patients with nonsurgical SSS, we found that the most sensitive and consistent indicator of sinus nodal dysfunction was the presence of sinus bradycardia on either the resting or ambulatory electrocardiogram. Nearly all of our patients also had syncope, palpitations, or both. During electrophysiologic study, 1 patient had a definitely abnormal sinoatrial conduction time, and the maximal corrected sinus nodal recovery time was prolonged in 6 of our patients.

Bharati et al[19] reported pathologic findings in 2 adolescents without congenital heart disease who had a history of sinus nodal dysfunction. At necropsy, each patient had an essentially normal sinoatrial node and sinoatrial nodal artery. However, each patient had significant pathologic changes in the atrial muscle and in the atrioventricular perinodal tissue. Others[20,21] have found abnormalities of the sinus node and atrial muscle in patients known to have clinical sinus nodal dysfunction. In the present series of patients with nonsurgical SSS, we have demonstrated not only common, significant abnormalities of the sinus node, but also significant albeit uncommon electrophysiologic abnormalities of the atrium. We also found mildly ab-

normal atrioventricular nodal function in many of our patients. The atrial pacing cycle length at which atrioventricular nodal Wenckebach occurred was a particularly sensitive indicator of atrioventricular nodal abnormality.

Based on our review of patients with SSS, we suggest that the presence of sinus bradycardia on resting or ambulatory electrocardiograms is the most sensitive indicator of sinus nodal abnormality. Symptoms such as syncope, palpitations, and chest pain are also nearly always present.

During electrophysiologic study, the maximal corrected sinus nodal recovery time may often be abnormally prolonged. However, some patients with sinus bradycardia and symptoms have normal maximal corrected sinus nodal recovery time. It is possible that the sedation used for our electrophysiologic studies decreases vagal tone and masks significant sinus nodal abnormalities. Our work in chronically instrumented animals found a 50% decrease in corrected sinus nodal recovery time after similar sedation.[22] In the patients in whom it was measured, the sinoatrial conduction time was a relatively insensitive indicator of sinus nodal function.

In this group of pediatric patients with nonsurgical sinoatrial nodal disease, we found a greater incidence of atrial and atrioventricular nodal disease than in our series of patients with SSS after the Mustard operation.[4] These findings, together with those of Bharati et al,[19] suggest that the process causing SSS in children not operated on is more diffuse than in patients who undergo Mustard operation. However, Vetter et al[23] found that some patients after the Mustard operation did have atrial and atrioventricular nodal disease associated with sinus nodal dysfunction. In the present series, electrophysiologic studies also confirmed tachyarrhythmias in patients with nonsurgical SSS and clarified the mechanism of these arrhythmias. Several tachyarrhythmias were found to be due to accessory connections.

In summary, we recommend that patients with either symptoms or electrocardiographic findings suggesting sinoatrial nodal dysfunction should be evaluated by electrophysiologic study. During electrophysiologic study, sinoatrial node, atrial muscle, and atrioventricular nodal function should be evaluated. Proper choice of antiarrhythmic drug therapy or permanent pacing procedure depends on a complete analysis of all components of the cardiac conduction system in patients with SSS. Although our results with both atrial and ventricular pacing have been satisfactory, the perfection of the universal pacemaker may dictate its use in these patients in the future.

Sustained Ventricular Tachycardia After Repair of Tetralogy of Fallot: New Electrophysiologic Findings

JOHN D. KUGLER, MD, WILLIAM W. PINSKY, MD, JOHN P. CHEATHAM, MD, PHILIP J. HOFSCHIRE, MD, PAUL K. MOORING, MD, and WILLIAM H. FLEMING, MD

Ventricular arrhythmia originating from the outflow tract of the right ventricle is a presumed cause of late sudden death in patients after repair of tetralogy of Fallot. Exercise testing has been shown to enhance detection, and phenytoin has been shown to control ventricular arrhythmias in these patients. This study reports new findings in 3 patients who underwent electrophysiologic studies at postoperative cardiac catheterization; in each, sustained ventricular tachycardia was induced and found to originate from the inflow-septal area of the right ventricle. Using serial studies, the same sustained ventricular tachycardia was induced during therapeutic serum concentrations of phenytoin but not after propranolol. No patient had ventricular arrhythmia during a 24-hour electrocardiogram or during exercise. Although no patient had normal hemodynamic function, only 1 patient had right ventricular pressure greater than two-thirds systemic pressure. Each patient had undergone initial intracardiac repair at a relatively late age (3, 9, and 9 years).

An increasing amount of evidence suggests that ventricular arrhythmia originating from the right ventricular outflow area is a cause of late sudden death in patients after repair of tetralogy of Fallot.[1–5] Recent attention, therefore, has been focused on the detection, prevention, and treatment of ventricular arrhythmias in these patients.[6–16]

Detection of ventricular arrhythmias has been enhanced by utilizing exercise testing and 24-hour ambulatory tape monitoring.[5–8,10,11,13] However, few intracardiac electrophysiologic data have been correlated with the noninvasive tests, making it difficult to assess the sensitivity of these tests in detecting life-threatening ventricular arrhythmias.[14] Although phenytoin has been shown empirically effective in controlling ventricular premature beats and ventricular tachycardia (VT) in these patients,[8,13] there have been no reported intracardiac electrophysiologic studies documenting the effectiveness of phenytoin. Several studies of adult patients with VT have been reported showing a strong positive correlation between the effectiveness of an antiarrhythmic agent during electrophysiologic study and the effectiveness during clinical application.[17–20] We describe herein new electrophysiologic findings in postoperative patients with tetralogy of Fallot in whom VT was induced during electrophysiologic study.

From the Sections of Pediatric Cardiology and Cardiac-Thoracic Surgery, Departments of Pediatrics and Surgery, University of Nebraska Medical Center, Omaha, Nebraska. Manuscript received March 30, 1982; revised manuscript received December 21, 1982, accepted December 22, 1982.

Address for reprints: John D. Kugler, MD, Section of Pediatric Cardiology, University of Nebraska Medical Center, Omaha, Nebraska 68105.

Methods

Patients: Sustained VT was induced during electrophysiologic studies in 3 adolescent patients: Patient 1, a 14-year-old boy, and Patients 2 and 3, 16-year-old and 14-year-old girls, respectively. Patients 1, 2, and 3 underwent initial intracardiac repair of tetralogy of Fallot at ages 9, 3, and 9 years of age, respectively. Patients 1 and 3 each underwent reoperation at age 12 years, and Patient 2 had a repeat operation at age 11 years. In Patients 2 and 3, a valved (Hancock) conduit was placed from the right ventricle to the pulmonary artery at the first operation and replaced at the second operation because of progressive stenosis between the right ventricle and the pulmonary artery. Patient 1 had a right ventricular outflow patch placed at the first operation but because of increasing cardiomegaly due to progressive pulmonary insufficiency and tricuspid insufficiency, porcine Carpentier-Edwards prosthetic tricuspid and pulmonary valves were placed at the second operation. Only Patient 2 had a residual ventricular septal defect after the first operation and, although reclosure was attempted during the second operation, a tiny residual ventricular septal defect persists.

Intracardiac electrophysiologic study: Meperidine (2 mg/kg, maximum 80 mg) and promethazine (1 mg/kg, maximum 40 mg) were administered to each patient 30 to 45 minutes before cardiac catheterization. All cardioactive drugs were

TABLE III Ventricular Tachycardia

Patient	CL (ms)	Induced by (ms)	Terminated by
1	220	S_2-S_3 220 (S_1-S_1 500; S_1-S_2 250)	DC CV
2	210	S_2-S_3 200 (S_1-S_1 500; S_1-S_2 250)	S_1-S_1 300
3	220	Burst (230)	DC CV

CL = cycle length; DC CV = direct-current cardioversion; S_1-S_1 = ventricular pacing cycle length; S_1-S_2 = interval ending with first premature ventricular stimulus; S_2-S_3 = interval ending with second premature ventricular stimulus.

stopped at least 36 hours before performing baseline electrophysiologic studies. The hemodynamic study was performed before and the angiographic study after the electrophysiologic studies.

Five quadripolar catheters were used in each patient during the initial electrophysiologic studies. After introduction by the percutaneous technique and under the guidance of fluoroscopy, 4 catheters were advanced through sheaths from both femoral veins and positioned in the following areas: (1) high right atrium near the sinoatrial node; (2) across the tricuspid valve orifice in order to record the low septal right atrial, His and right ventricular inflow-septal depolarizations; (3) the right ventricular apex; and (4) the right ventricular outflow tract. The interelectrode distances were 10 mm on the His catheter and 3 mm on the right ventricular apex and outflow tract catheters. For recording, the proximal pair of electrodes on the right ventricular apex catheter and the distal pair on the right ventricular outflow tract catheter (positioned anteriorly) were used and both distal and proximal pairs were used on the His catheter. Through a side-arm sheath placed in a femoral artery, the fifth catheter was advanced retrogradely and positioned in the lateral left ventricle. Surface electrocardiographic leads I, aVF, and V_1 were recorded simultaneously with the electrograms on an Electronics for Medicine photographic recorder (VR12 or VR16) at a paper speed of 100 or 250 mm/s.

Ventricular stimulation techniques: A programmable stimulator (Bloom Associates, Philadelphia) was used to deliver stimuli 1 ms in duration with amplitude approximately twice diastolic threshold (no amplitudes were >2 mA). After evaluation of the sinoatrial node, atrial muscle, atrioventricular node, and the His-Purkinje system, ventricular stimulation was performed.

Ventricular stimulation protocol: 1. Single (S_2) and double (S_2-S_3) premature stimuli were induced into a ventricular paced rhythm (2 cycle lengths: 500 and 400 ms); S_2 was coupled to the last ventricular paced beat (S_1) and S_1-S_2 was decreased by 10 to 20 ms until failure of S_2 capture (ventric-

ular muscle effective refractory period). The S_1-S_2 interval then was increased 50 to 70 ms and S_2-S_3 were initiated at the same interval, followed by successive 10 to 20 ms decrements. When failure of S_3 capture occurred, S_1-S_2 was decreased, followed again by a decrease in S_2-S_3 until both S_2 and S_3 failed to capture.

2. Rapid ventricular pacing was carried out at several cycle lengths (400 to 200 ms). At cycle lengths of 300 to 400 ms, the duration of pacing was approximately 15 to 30 seconds. To avoid hypotension associated with longer duration of pacing at the shorter cycle lengths, bursts of 8 paced beats were given. No fewer than 5 bursts were given at each cycle length (range of cycle length 280 to 200 ms).

Administration of antiarrhythmic drugs and timing of electrophysiologic studies: After baseline study, serial drug-electrophysiologic studies were carried out in the sequence listed in Table I. A drug was considered successful when no more than 2 reproducible ventricular beats were induced.

Results

Noninvasive detection of ventricular arrhythmias before electrophysiologic study: Patient 1 had no premature ventricular beats on 24-hour ambulatory monitor tape recording, and Patient 2 had a total of 1 premature ventricular beat recorded during the 24 hours. Patient 3 had a total of 30 premature ventricular contractions over 24 hours; none were associated with symptoms. No patient had ventricular arrhythmia immediately before or during treadmill exercise testing, although Patient 2 had 10 uniform, fixed coupled premature ventricular contractions during the third minute of postexercise recording. (This patient subsequently underwent repeat treadmill exercise testing after a therapeutic serum concentration of phenytoin was achieved; no premature ventricular beats or VT occurred before, during, or after exercise.)

Electrophysiologic findings: *Baseline intervals:* The baseline surface and intracardiac intervals are listed in Table II. No patient had normal measurements.[23] No specific intracardiac interval consistently was prolonged in each patient, although each patient did have a prolonged QRS duration on the surface electrocardiogram. In addition, 2:1 atrioventricular block within the atrioventricular node occurred in Patient 1 at an atrial pacing rate of 150 beats/min, indicating atrioventricular nodal dysfunction.

Ventricular tachycardia: The basic data are listed in Table III. The rate of the sustained ventricular tachycardia was fast in each patient ranging from 272 to 286 beats/min. The earliest ventricular activation was recorded in each patient by the distal and proximal electrodes on the catheter positioned across the tricuspid valve (Fig. 1 to 3). During sinus rhythm, this catheter recorded low septal right atrial, His, and right ventricular inflow-septal depolarizations (Fig. 1 and 2). In Patients 1 and 2, increased diastolic depolarizations in this right ventricular inflow-septal area during VT provided greater difficulty in determining onset of the depolarization. However, the initial beat of the VT was identifiable (Fig. 1 to 3). Moreover, after procainamide in Patient 1 and after phenytoin in Patient 2, the earliest activation was clearly delineated (Fig. 2 and 3). In each instance, the structure of the QRS in V_1 was of left bundle branch block. No patient had evidence of retrograde ventriculoatrial conduction during either ventricular tachycardia or ventricular pacing at any rate.

The VT was terminated by synchronized direct current cardioversion in Patients 1 and 3 because hypotension-associated symptoms (confusion and chest pain) did not allow time for ventricular stimulation techniques to be used.

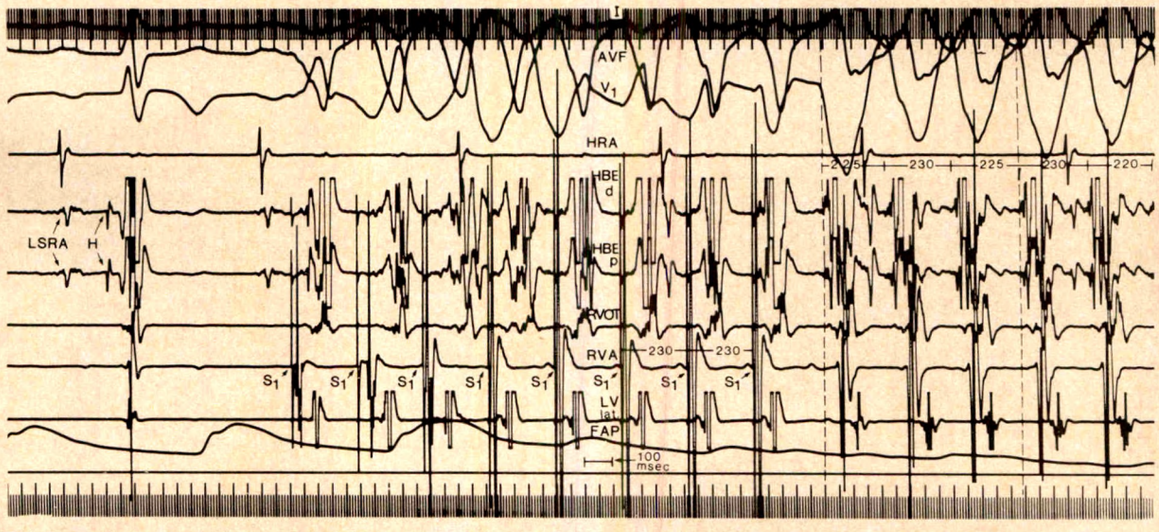

FIGURE 1. Recording of the initiation of VT in Patient 3 before administration of antiarrhythmic agents. After 8 beats of rapid ventricular stimuli (S_1) at 230 ms cycle length, sustained VT is induced at a similar cycle length. The earliest site of activation of the initial beat (**first dashed vertical line**) is recorded by the electrodes which recorded the His potential during sinus rhythm and, therefore, is in the right ventricular inflow-septal area. This activation is unchanged with further beats (for example, shown by the **second dashed line**). The QRS structure is one of left bundle branch block. AVF = surface electrocardiographic lead aVF; FAP = femoral artery pressure; H = His bundle; HBE_d and HBE_p = recording from the distal (d) and proximal (p) pair of electrodes on the His bundle catheter; HRA = high right atrium; I = surface electrocardiographic lead I; LSRA = low septal right atrium; LV lat = lateral left ventricle; RVA = right ventricular apex; RVOT = right ventricular outflow tract; S_1 = ventricular extrastimulus.

Serial drug studies: Electrophysiologic findings: *Intervals:* The changes are listed in Table II.

Ventricular stimulation after phenytoin and propranolol: The findings are listed in Table IV.

Ventricular stimulation after lidocaine, procainamide, and quinidine: Patient 1 was the only patient who underwent repeat electrophysiologic studies after drugs other than propranolol and phenytoin. (After it was found that propranolol prevented and phenytoin did not prevent VT, Patients 2 and 3 did not undergo further serial electrophysiologic studies.) Although the rate was slower, ventricular tachycardia occurred after each of these antiarrhythmia agents. Therapeutic serum concentrations were present after administration of procainamide and quinidine and none were measured after lidocaine. Conversion of VT by ventricular stim-

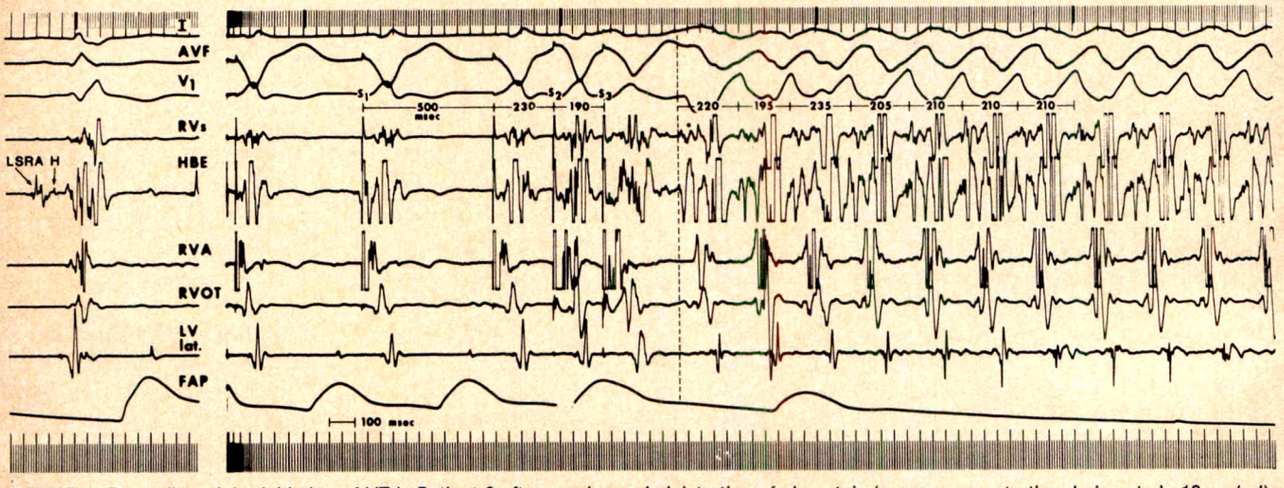

FIGURE 2. Recording of the initiation of VT in Patient 2 after previous administration of phenytoin (serum concentration during study 19 μg/ml). One sinus beat is recorded, then the last 3 beats of 8 beats of ventricular paced rhythm of 500 ms (S_1-S_1) are recorded. After the last S_1, a premature ventricular beat (S_2) is given 230 ms later, followed by a second premature beat (S_3) 190 ms later. Sustained VT is induced at a cycle length of 210 ms. The earliest activation (**vertical dashed line**) is recorded by the 2 catheters recording right ventricular inflow-septal activity: one is by the catheter which has been moved from the high right atrium (lack of ventriculoatrial conduction had been previously noted during baseline study) to the right ventricular inflow-septal area (RVs). This catheter is positioned within 1 cm of the catheter which is recording the low septal right atrial (LSRA), His (H), and right ventricular inflow-septal depolarization during sinus rhythm and, therefore, also is recording the earliest activation during VT. The duration of each ventricular depolarization in this area is long during sinus rhythm and is almost continuous during tachycardia. Left bundle branch block pattern is noted during tachycardia. Abbreviations are as in Figure 1.

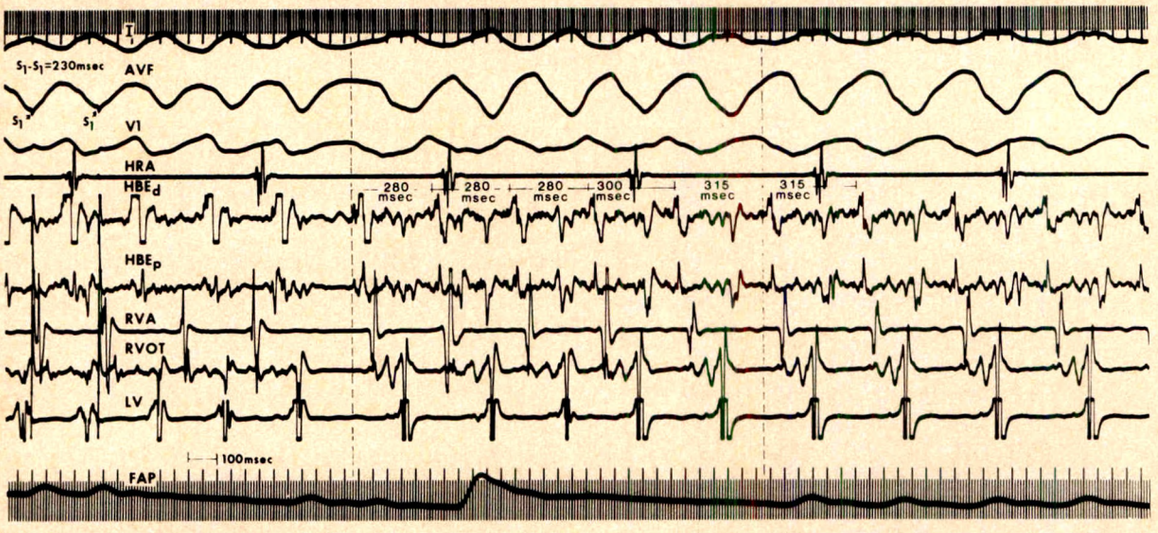

FIGURE 3. Recording of the initiation of VT in Patient 1 after administration of procainamide (serum concentration 7 μg/ml during study). After 8 beats of rapid right ventricular apex pacing (S_1-S_1 230 ms), ventricular tachycardia is induced. After 2 beats that appear to originate from the right ventricular apex, the sustained tachycardia is noted to originate from the right ventricular inflow-septal area because the earliest ventricular activation (**first dashed vertical line**) is recorded by the electrodes on the catheter which recorded the His depolarization during sinus rhythm. The depolarizations from this area are almost continuous. After several beats, the cycle length of the tachycardia lengthens and stabilizes at 315 ms. The earliest activation continues to exist in the inflow-septal area as shown by the **second vertical dashed line.** The QRS complexes are of a left bundle branch structure during the tachycardia. Abbreviations are as in Figure 1.

ulation techniques was unsuccessful after lidocaine, but successful after procainamide and quinidine.

Hemodynamic and angiographic findings (Table V): No patient had normal hemodynamic findings, although Patient 1 only had 2 borderline abnormalities: decreased cardiac index (Fick)[24] and mildly increased right ventricular systolic pressure. Patient 2 had one-half systemic right ventricular systolic pressure, and end-diastolic pressure also was increased. Increased peak systolic and end-diastolic right ventricular pressures were found in Patient 3. The Fick cardiac index was measured before and after propranolol in this patient, and no change was evident (2.02, 2.03 liters/min/m^2, respectively).

Results of treatment: Long-term oral propranolol therapy was initiated in each patient and doses were adjusted to maintain serum concentrations above those obtained during electrophysiologic studies when no VT was induced. Because of induction of sinus and exacerbation of atrioventricular node dysfunction by propranolol, Patient 1 received a permanent ventricular demand pacemaker before dismissal. In the follow-up period (6 to 12 months), each patient has had at least three 24-hour ambulatory electrocardiograms. 2 M-mode echocardiograms, and 1 treadmill exercise test.

Patient 1 has had no adverse effects and each of his noninvasive tests have shown no changes except that during the treadmill test he was able to exercise 1 minute longer compared with his endurance before propranolol. His rhythm remains sinus and he seldom has ventricular paced rhythm at 60 beats/min. His left ventricular function remains good by echocardiogram (shortening fraction unchanged at 40%). The dimensions of his right and left ventricles also are unchanged. Patient 2 also has had no adverse effects. Although the dimensions of her left and right ventricles as well as her shortening fraction are unchanged on echocardiogram, her duration of exercise to exhaustion was shortened by 1.5 minutes compared with baseline values. Patient 3 has had continuation of nonspecific substernal chest pain unrelated to activity or to dysrhythmia as documented by repeat 24-hour ambulatory electrocardiogram and treadmill testing. Rare premature ventricular and atrial beats (average <1 per hour) have been present on several 24-hour electrocardiogram recordings. Her exercise tolerance is essentially unchanged (duration 0.5 minute less than baseline) and her echocardiographic indexes are also unchanged.

Discussion

Several new findings are apparent from this study in 3 adolescents who had undergone surgical repair for tetralogy of Fallot. Despite the absence of significant premature ventricular beats and no VT by noninvasive tests, sustained reproducible VT was induced during electrophysiologic studies. The site of origin was consistently found in the right ventricular inflow-septal area rather than in the outflow tract, and hemodynamic data showed significant right ventricular hypertension in only 1 patient. Propranolol, but not phenytoin, prevented the induction of VT.

Ventricular arrhythmias in patients after repair of tetralogy of Fallot: Depending on the reported series, sudden death in the late postoperative period has accounted for 30 to 75% of late deaths in patients who have undergone repair of tetralogy of Fallot.[1–5] Although some investigators have questioned the association of sudden death with ventricular arrhythmias,[9] many others have reported data to support strongly the hypothesis that premature ventricular beats leading to VT and fibrillation are the likely terminal events in most of these patients.[1–5] Therefore, it is important to detect these ventricular arrhythmias.

TABLE IV Effect of Phenytoin and Propranolol

Patient	Phenytoin (μg/ml)	VT CL (ms)	Induced by (ms)	Terminated by (ms)	Propranolol (ng/ml)	VT
1	22	250	Burst (250)	S_1-S_1 230 (after PA & VT CI 315)	154	...
2	19	210	S_2-S_3 190 (S_1-S_1 500; S_1-S_2 230)	S_1-S_1 250 → VF → defib	49	...*
3	21	240	Burst (230)	DC CV	56	...

* Immediately after propranolol, ventricular tachycardia was induced: 1 burst of 220 ms. Thirty minutes later, without any further drug, no VT could be induced.

DC CV = direct-current cardioversion; defib = defibrillation (direct-current); CL = cycle length; PA = procainamide; S_1-S_1, S_1-S_2, S_2-S_3 (see Table III); VF = ventricular fibrillation; VT = ventricular tachycardia.

TABLE V Hemodynamic Data

Patient	RV (mm Hg)	MPA (mm Hg)	PAW (mm Hg)	LV (mm Hg)	Ao (mm Hg)	CI* (liters/min/m^2)
1	40/0,8	25/8 (14)	(7)	100/0,10	100/80 (92)	2.56
2	65/0,12	34/12 (18)†	(14)	...	132/75 (95)	4.54
3	85/0,10	70/15 (35)‡	(9)	100/0,10	100/70 (82)	2.02

Values in parentheses represent mean pressure.

* Calculated by Fick equation (oxygen consumption measured by flow-through technique).

† Right ventricular-main pulmonary artery conduit 80/8 (30).

‡ Right pulmonary artery 28/14 (18).

Ao = aorta; CI = cardiac index; LV = left ventricle; MPA = main pulmonary artery; PAW = pulmonary arterial wedge; RV = right ventricle.

Garson,[11] James,[7] Kavey,[6] and their co-workers have shown that exercise testing is a useful method to detect dysrhythmias in patients who have undergone repair of tetralogy of Fallot. These investigators reported that premature ventricular beats (uniform and multiform) as well as VT were induced during exercise. In the study of Garson et al,[11] the ability to detect ventricular dysrhythmia doubled with exercise compared with resting standard electrocardiogram (30% versus 14% of 104 patients, respectively). In our patients, neither exercise nor surface electrocardiogram (including 24-hour tape recording) were sensitive methods of detecting ventricular dysrhythmias. Based on these data, underlying life-threatening ventricular arrhythmia may not be detected by noninvasive testing.

Intracardiac electrophysiologic studies: Except for the reports by Garson et al[14] and by Vetter and Horowitz,[15] the only other extensive electrophysiologic study in patients who have had VT after repair of tetralogy of Fallot was reported by Horowitz et al.[9] They found that the reentry VT originated from the right ventricular outflow tract in each of their 4 patients. To our knowledge, our study is the first to show VT originating from the right ventricular inflow-septal area in patients who have had repair of tetralogy of Fallot. This likely is near the site of the patch repair of previous ventricular septal defect. Patients 2 and 3 had undergone anterior conduit insertion in the right ventricular outflow tract but activation clearly was later in this area compared with the inflow area. As in the patients in the reports by Horowitz,[9] Josephson,[25] and their co-workers, continuous electrical activity in the area of originating VT was found. Based on this finding as well as on the methods of initiation and termination which were also similar to those of other investigators,[9,18–20,25] the mechanism of the tachycardia appears to be reentry.

Other electrophysiologic findings in our patients were similar to those reported by Gillette et al,[3] and recently by Garson et al[14] and by Vetter and Horowitz[15]: abnormalities were evident throughout the conduction system. Although the hemodynamic data (especially increased right ventricular systolic pressure) were not as consistently abnormal in our patients as they have been reported earlier by Garson et al,[4] perhaps both hemodynamic and conduction system abnormalities are of importance: they may signal underlying ventricular muscle disease, thus predisposing these patients to VT. Because our patients each had undergone repeat intracardiac operations, they may represent a more severe subset of patients who have had repair of tetralogy of Fallot.

Serial drug studies: Before this study, no serial electrophysiologic studies have been reported in tetralogy of Fallot patients who have VT and in whom therapeutic concentrations of phenytoin or propranolol have been achieved. Horowitz et al[9] performed serial drug electrophysiologic studies but each specific drug is not stated. However, they did find that procainamide was successful in preventing induction of VT in 2 of 4 patients. In our study, because propranolol was the only drug that prevented VT in Patient 1, it was used initially in each of the other 2 patients. Further testing with other antiarrhythmic agents was not carried out in these patients because propranolol was found effective. Although Patient 1 had tachycardia induced when a therapeutic procainamide concentration was present, it is possible that if a very high procainamide serum concentration had been achieved, tachycardia may have been prevented.[26,27]

Because of the excellent results in clinical studies reported by Garson,[5,8] Rocchini,[13] and their co-workers, it was unexpected that VT was not prevented by phenytoin. Because Garson et al[5] found serum concentrations of 15 to 20 μg/ml effective in controlling clinical ventricular arrhythmias and because each of our patients had concentrations of ≥19 μg/ml during induction of sustained VT, it is unlikely that too low serum concentrations were achieved in our patients. Neither Garson et al[5,8] nor Rocchini et al[13] carried out electrophysiologic studies in patients taking phenytoin. Therefore, no comparisons can be made regarding inducibility of VT during electrophysiologic studies. It is possible that clinical control of VT by phenytoin does not correlate with control as determined during electrophysiologic studies. Patient 2 in our study did not have premature ventricular beats after the treadmill exercise test, carried out while she was taking phenytoin, and the conclusion may have been made that phenytoin was the drug to choose for long-term therapy. However, because VT again was induced in this patient during electrophysiologic study (when the phenytoin serum concentration was 19 μg/ml), but propranolol was found effective, we chose propranolol as the drug for chronic treatment.

In adult patients, recent data have shown amiodarone is successful in clinically controlling chronic VT.[28,29] However, the effective clinical control does not correlate in many patients with the ease of tachycardia inducibility during invasive electrophysiologic studies.[29] In contrast, data in patients treated with multiple other antiarrhythmic agents have supported the concept of direct correlation between inducibility during electrophysiologic studies and clinical effectiveness.[7–10] To our knowledge, no studies have been reported regarding phenytoin and this relation. We cannot make any conclusions at this point, because our patients had no evidence of clinical VT.

It may be argued that antiarrhythmic treatment is not indicated in patients who have no evidence of clinical VT. Our goal is to prevent sudden death. Based on available data supporting the hypothesis that ventricular arrhythmia is a cause of sudden death in patients who have had earlier repair of tetralogy of Fallot, we believe that treatment should be given if the treatment is well tolerated. The follow-up in these patients shows no exacerbation of preexisting problems as well as no appearance of new problems while receiving chronic propranolol therapy. Longer duration of follow-up is needed, however, before firm conclusions are made.

Acknowledgment: We thank Bob West, Steve Jones, Lynn Rozler, and Jan Carr for their expert assistance in the Cardiac Electrophysiology Laboratory, and Jim Griess, Janie Pillen, Jean Puls, Candy Heston, Joan Steffensmeier, and Melody Barnett for their superb endeavors in developing and pro-

cessing. We especially thank Cathy Blodgett, RN and Mary Fry for their invaluable time and effort in preparing the manuscript.

Right Ventricular Function in Adults With Pulmonary Hypertension With and Without Atrial Septal Defect

MARVIN A. KONSTAM, MD, JOHN IDOINE, ScD, JOSHUA WYNNE, MD, WILLIAM GROSSMAN, MD, LAWRENCE COHN, MD, J. ROBERT BECK, MD, JOSEPH KOZLOWSKI, RT, and B. LEONARD HOLMAN, MD

Using equilibrium (gated) radionuclide ventriculography, right ventricular (RV) function was studied in 22 adults with pulmonary hypertension and in 16 patients without evidence of cardiac disease. To assess the effect of volume overload on RV performance in pulmonary hypertension, RV ejection fractions were compared in patients with and without left-to-right shunts due to atrial septal defect (ASD). In addition, the effect of ASD repair on RV function was examined. In 14 patients with pulmonary hypertension without RV volume overload (group I), the RV ejection fraction (0.35 ± 0.11, mean ± standard deviation [SD]) was significantly lower than in the normal group (0.47 ± 0.11, $p < 0.01$). In 8 patients with left-to-right shunts due to ASD (group II) and with RV systolic pressures similar to those in group I, the mean RV ejection fraction (0.53 ± 0.15) was normal and was significantly higher than in group I ($p < 0.01$). Right ventricular end-diastolic volumes, estimated from combined radionuclide and hemodynamic data, were higher ($p < 0.01$) in group II patients (171 ± 70 ml/m^2) than in group I patients (70 ± 13 ml/m^2). In 5 patients who underwent isolated shunt repair, mean RV ejection fraction decreased postoperatively from 0.57 ± 0.17 to 0.40 ± 0.12 ($p < 0.05$). It is concluded that (1) pulmonary hypertension frequently causes a decrease in RV systolic function due to abnormal afterload; (2) in patients with RV volume overload due to left-to-right shunt, systolic function, as measured by the ejection fraction, remains normal despite pulmonary hypertension, possibly through the Starling mechanism; and (3) RV systolic function often decreases after repair of an ASD.

Abnormally high afterload, or systolic wall stress,[1] may result in depression of ventricular systolic performance. Right ventricular (RV) function has been found depressed in some patients with pulmonary arterial hypertension.[2–4] This depression of systolic performance is probably the direct result of increased afterload, since normal RV contractility has been found in patients with pulmonary hypertension and RV failure.[5,6] Furthermore, RV function often improves after relief of abnormal afterload.[7]

When pulmonary arterial hypertension occurs in the setting of a significant left-to-right shunt due to atrial septal defect (ASD), abnormally high RV afterload and preload may coexist. The manner in which abnormal preload, or diastolic filling, influences the relation between RV afterload and systolic performance has not been defined. Using radionuclide ventriculography, we studied RV function in adults with mild to severe pulmonary arterial hypertension. We compared ejection fractions in patients with and without significant atrial-level left-to-right shunts to assess the influence of abnormal preload in groups with similar degrees of RV systolic hypertension. In addition, we examined the effect of surgical relief of volume overload on RV function in patients with pulmonary hypertension.

Methods

Subjects: We studied 22 patients with pulmonary arterial hypertension (systolic pressure ≥35 mm Hg) who underwent cardiac catheterization (Table I). Patients with coronary artery disease were excluded. Pulmonary and systemic blood flows were calculated using the Fick method.[8] Group I comprised 14 patients without evidence of RV volume overload. Left-to-right shunts were excluded by oximetry in all. Group II comprised 8 patients with ASD, pulmonary to systemic blood flow ratios of at least 1.8, and RV systolic pressures of at least 35 mm Hg. Group III consisted of 16 control subjects, 8 men and 8 women, ranging in age from 27 to 71 years (mean 51 ± 13), who underwent radionuclide ventriculography. All group III patients underwent cardiac catheterization because of chest pain and were found to have normal coronary arteries, normal hemodynamic features, and normal left ventricular ejection fractions (≥0.50).

Radionuclide studies: Initial radionuclide studies were performed within 1 week of cardiac catheterization except in Patient 15, whose radionuclide examination was performed 2 months after catheterization, but in whom no clinical change had occurred in the interval. Seven of 8 group II patients consented to postoperative repeat radionuclide ventriculog-

AR = aortic regurgitation; 1° ASD = ostium primum atrial septal defect; 2° ASD = ostium secundum atrial septal defect; COPD = chronic obstructive pulmonary disease; MR = mital regurgitation; MS = mitral stenosis; MVA = mitral valve area; NYHA = New York Heart Association; PAPV = partially anomalous pulmonary venous return; PBF = pulmonary blood flow; PPHT = primary pulmonary hypertension; PS = pulmonary stenosis; PVR = pulmonary vascular resistance; Qp/Qs = pulmonary to systemic blood flow ratio; RA = mean right atrial pressure; RVEF = right ventricular ejection fraction; RVs = right ventricular systolic pressure; VSDR = status after ventricular septal defect repair.

raphy. Five patients were studied 4 to 8 days after surgery, and 2 patients were studied 2 months (Patient 20) and 4 months (Patient 15) after surgery.

Red blood cells were labelled in vivo by intravenously injecting unlabelled stannous pyrophosphate (5 mg Pyrolite, New England Nuclear, Boston, Massachusetts) followed by 15 to 25 mCi of technetium-99m as pertechnetate 15 to 20 minutes later.[9] Gated radionuclide ventriculograms were obtained with an Anger scintillation camera and a high-sensitivity straight-bore, 30° slant-hole collimator (Engineering Dynamics, Lowell, Massachusetts), using a previously described technique.[10] Using a modified left anterior oblique projection (30° caudal tilt), 10 million counts were acquired in a 64 × 64 matrix mode on magnetic disk (PDP 11/34 and Gamma-11 system, Digital Equipment, Maynard, Massachusetts). Data acquisition was physiologically gated to the patient's electrocardiogram, with the cardiac cycle divided into 25 ms frames.

Right ventricular ejection fractions were measured by a method similar to that of Slutsky et al.[11] A preliminary RV region-of-interest was manually drawn on the end-diastolic frame, using a computer joy-stick. A preliminary RV frame-activity curve was generated, permitting selection of end-diastolic and end-systolic frames. A stroke volume image, derived by computer subtraction of the end-systolic from the end-diastolic frame, depicted the ventricular regions, and a paradox image, derived by computer subtraction of the end-diastolic from the end-systolic frame, depicted atrial regions.[12,13] A summation of the stroke volume and paradox images, which aided in delineating the right atrioventricular plane, was used to redraw the RV region-of-interest, if necessary (Fig. 1). A 3-pixel wide background region was drawn immediately adjacent to the RV region (Fig. 1). At its superior margin, the background region was adjacent to the RV outflow tract. It extended along the lateral and inferior RV borders, but not the interventricular septum. Background was subtracted using counts/pixel in the background region at the end-systolic frame, and the ejection fraction was calculated as (EDC − ESC)/EDC, where EDC and ESC are background-corrected RV end-diastolic and end-systolic counts, respectively. We have found excellent correlation between this method of calculating RV ejection fraction and the first-pass method of Tobinick et al[14] (r = 0.91) in a group of 30 patients, including patients with RV dilatation due to valvular or congenital heart disease, pulmonary disease, or cardiomyopathy. Intraobserver correlation was excellent (r = 0.98, standard error of the estimate = 0.04). For those patients in whom the heart rate during radionuclide study was within 10% of the heart rate during catheterization, RV end-diastolic volume (EDV) was estimated from pulmonary blood flow (PBF) and heart rate (HR) measured during catheterization: RVEDV (ml/m^2) = [PBF (ml/min/m^2)]/[HR (min^{-1}) × RV ejection fraction] (Equation 1).

The ratio of right-to-left ventricular end-diastolic counts was used to estimate postoperative changes in relative ventricular end-diastolic volumes. Background-corrected RV end-diastolic counts were calculated as described above. The end-diastolic left ventricular perimeter was drawn manually, and the left ventricular background regions were defined automatically using a previously described computer algorithm.[12] The left ventricular region was redrawn, if necessary, on an ejection fraction image,[12] and background regions were redefined as before. Background was subtracted using average counts/cell in the background regions at the left ventricular end-systolic frame, and left ventricular end-diastolic counts was calculated.

Statistical methods: Comparisons of RV ejection fractions and of hemodynamic data in the 3 patient groups were made

using 1-way analysis of variance.[15] When the hypothesis of equal treatment means was rejected, the contrast method of Scheffe[16] was used to determine the proportional contribution of each patient group to the overall effect on the analysis of variance. In addition, significant contributions to the variance were examined using 2 sample t tests. Preoperative and postoperative radionuclide measurements were compared using the paired t test.

Results

Hemodynamic data are presented in Table I. Right ventricular systolic pressures were similar in groups I (average 60 ± 23 mm Hg [SD]) and II (average 60 ± 25 mm Hg). Patient 22 had pulmonary stenosis with a 24 mm Hg peak-to-peak pulmonary valve gradient. In group I, pulmonary vascular resistance averaged 624 ± 891 dynes s cm^{-5}. In group II, pulmonary vascular resistance averaged 190 ± 225 dynes s cm^{-5}, although the difference from group I was not statistically significant using either parametric or distribution-free analysis. Each group II patient had a significant step-up in oxygen content (≥2.0 ml/100 ml) between mixed venous and right atrial blood samples, with the ratio of pulmonary to systemic blood flow ranging from 1.9 to 4.2 (mean 3.2 ± 0.8).

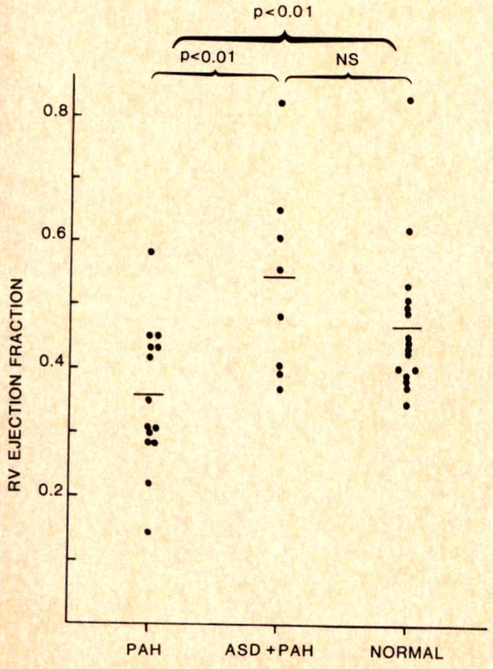

FIGURE 2. Comparison of right ventricular (RV) ejection fractions in patients with pulmonary arterial hypertension (PAH) without left-to-right shunt, in patients with pulmonary arterial hypertension and left-to-right shunt through an atrial septal defect (ASD), and in normal subjects.

Radionuclide data: In the group without evidence of cardiac disease (group III), RV ejection fractions averaged 0.47 ± 0.11 (Fig. 2). In group I, RV ejection fractions averaged 0.35 ± 0.11. In patients with ASD (group II), RV ejection fractions ranged from 0.37 to 0.79 (mean 0.53 ± 0.15). Mean RV ejection fractions were significantly different in the 3 groups ($p < 0.01$). According to the Scheffe contrast method, the significant contributors to this difference ($p < 0.05$) were, in order, group I versus II, group I versus II and III, and group I versus III. In 7 group I patients and 5 group II patients in whom heart rate during catheterization was within 10% of heart rate during radionuclide study, RV end-diastolic volumes were estimated by combining radionuclide and hemodynamic data according to equation 1. RV end-diastolic volumes were significantly larger ($p < 0.01$) in group II (171 ± 70 ml/m^2) than in group I (70 ± 13 ml/m^2).

All 8 group II patients underwent surgical repair of the ASD. Patient 15, with severe preoperative pulmonary hypertension, developed severe RV failure immediately after surgery, requiring isoproterenol and nitroprusside infusions for 4 days. The patient's condition subsequently improved and she was discharged on the 13th postoperative day. The remaining 7 patients had uneventful early postoperative courses. Two to 14 months postoperative follow-up demonstrated clinical improvement in all group II patients except Patient 22, in whom repeat catheterization 14 months after surgery showed a residual ASD with a pulmonary to systemic

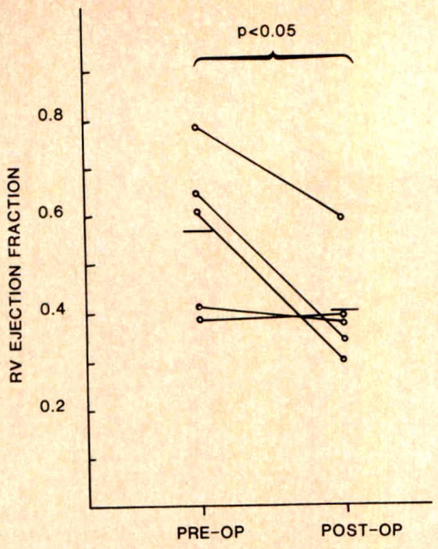

FIGURE 3. Comparison of preoperative (PRE-OP) and postoperative (POST-OP) right ventricular (RV) ejection fractions in patients who underwent isolated repair of atrial-level left-to-right shunts.

blood flow ratio of 1.5 and RV systolic pressure of 50 mm Hg.

Seven group II patients consented to repeat postoperative radionuclide ventriculography. In all 5 group II patients studied who underwent isolated ASD repair, postoperative RV ejection fractions decreased or remained unchanged compared with preoperative values (Fig. 3), with a mean decrease from 0.57 ± 0.17 to 0.40 ± 0.12 ($p < 0.05$). Right ventricular ejection fraction increased postoperatively in Patient 21 (0.48 to 0.64), who underwent replacement of a stenotic mitral valve and in Patient 22 (0.37 to 0.43), who underwent valvulotomy for pulmonic stenosis in addition to ASD repair.

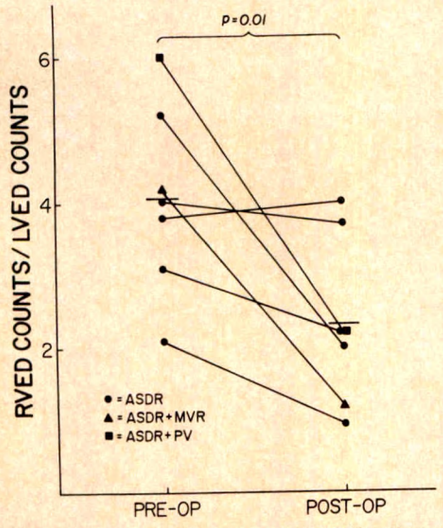

FIGURE 4. Comparison of preoperative (PRE-OP) and postoperative (POST-OP) ratios of right ventricular (RVED) to left ventricular (LVED) end-diastolic counts in patients who underwent ASD repair (ASDR). MVR = mitral valve replacement; PV = pulmonary valvulotomy.

The ratio of right-to-left ventricular end-diastolic counts decreased postoperatively from 4.1 ± 1.3 to 2.3 ± 1.2 ($p = 0.01$), indicating a postoperative decrease in RV end-diastolic volume, an increase in left ventricular end-diastolic volume, or both (Fig. 4 and 5).

Discussion

Our study indicates that RV systolic function, as assessed by the ejection fraction, is frequently depressed in adults with chronic pulmonary arterial hypertension. Since variables of RV performance which are relatively independent of afterload, such as the maximal rate of isovolumic pressure increase, are normal or elevated in chronic pulmonary hypertension,[5,6] depressed systolic function probably results directly from abnormally high systolic wall stress, rather than from depressed contractility. In patients with pulmonary hypertension and significant left-to-right shunts, our finding of normal RV ejection fractions suggests that the volume overloaded right ventricle maintains normal systolic function, despite increased afterload. After surgical repair of ASD in patients with pulmonary hypertension, RV function often declines.

Ventricular afterload, or systolic wall stress, is directly proportional to systolic pressure but is also related directly to chamber dimension and inversely to wall thickness.[1] Differences in chamber dimension and wall thickness probably account for much of the variability in RV performance which has been reported in the presence of pressure overload. Children with isolated pulmonic stenosis, who have severe RV hypertrophy, have been found to have normal or increased RV ejection fractions,[17,18] whereas in adults with pulmonary hypertension due to valvular heart disease or obstructive lung disease, RV ejection fractions have been found

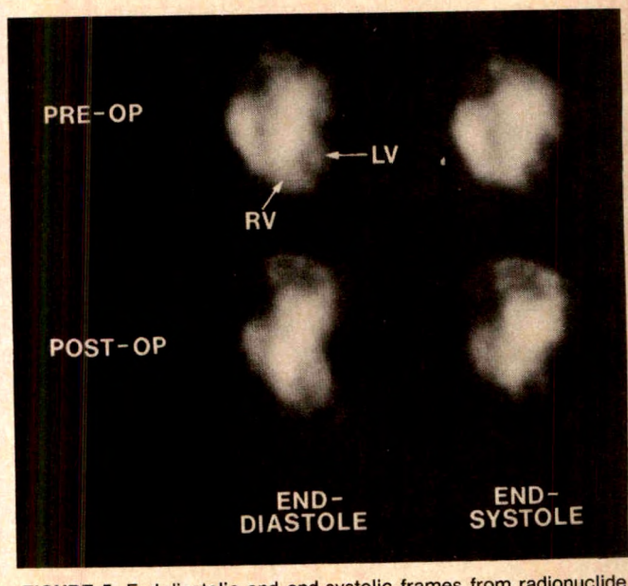

FIGURE 5. End-diastolic and end-systolic frames from radionuclide ventriculograms performed before and after ASD repair and mitral valve replacement in Patient 21. The postoperative study shows reduction in the volume of the previously dilated right ventricle (RV). LV = left ventricle.

to be variably depressed.[2–4] The depressed RV ejection fractions found in our group I patients are likely to be due to abnormal systolic pressure in the absence of adequate compensatory hypertrophy.

In contrast to group I, all of our group II patients with ASDs and predominant left-to-right shunts had normal RV ejection fractions despite pulmonary hypertension. The best explanation for this finding is that systolic performance was normalized by increased preload due to left-to-right shunting. This conclusion is supported by the larger RV end-diastolic volumes in group II and by the decrease in RV ejection fractions after ASD repair. Two additional explanations for the normal RV ejection fractions in group II must be considered. First, contractility may have been increased. This possibility is unlikely since chronic volume loading would be expected to depress contractile function. Secondly, systolic wall stress might have been normalized despite pulmonary hypertension. In group I, the development of pulmonary hypertension may have been insidious, with onset in early life, permitting greater degrees of RV hypertrophy. This increased wall thickness may have resulted in normalization of RV systolic wall stress and greater RV ejection fractions for the same degree of systolic pulmonary hypertension in group II compared with group I, in which pulmonary hypertension may have occurred later in life and more rapidly.

It has been suggested that the chronic volume load imposed by a left-to-right shunt may result in deterioration of RV systolic function.[19,20] Liberthson et al[19] found evidence of RV dysfunction in over half of their adult patients with ASD. However, in most of their patients, Liberthson et al assessed RV function subjectively. They employed a left anterior oblique view without caudal angulation, in which the overlap between the RV and the dilated right atrium is greater than in the caudally tilted view. Furthermore, in most cases they recorded images only at "end-systole" and "end-diastole." These intervals may not have coincided with the timing of peak and trough RV volumes, particularly in the presence of an RV conduction delay, which may accentuate the difference in timing between right and left ventricular end-systole. Both the greater overlap between right ventricule and right atrium, and the potential error in choosing RV end-systole, may result in underestimation of RV systolic function. From our findings, it is likely that patients in group II had some reduction in RV contractility, as evidenced by the decrease in the ejection fraction after surgical reduction in preload. However, our data do not support the contention that RV dysfunction due to chronic volume overload is a major problem in adults with ASD and significant left-to-right shunts.

Our finding of a reduction in RV ejection fraction postoperatively in the patients who underwent isolated ASD repair probably reflects a decrease in preload. Although a decrease in RV function resulting from myocardial ischemia during cardiopulmonary bypass cannot be excluded, our patients were restudied at least 4 days after surgery, at which time ischemic decrease in ventricular function would no longer be expected.[21,22] Postoperatively, RV ejection fraction increased in 1 patient who underwent mitral valve replacement for mitral stenosis and in 1 patient who underwent valvulotomy for pulmonic stenosis in conjunction with ASD repair. The effect of reduced RV afterload by these procedures may have outweighed the effect of preload reduction. The postoperative courses in our patients were similar to those described in previous studies, indicating the surgical repair of ASD in adults is safe and often produces clinical improvement.[19,23,24] In most patients, the postoperative decrease in RV ejection fraction was not sufficient to alter the clinical course adversely.

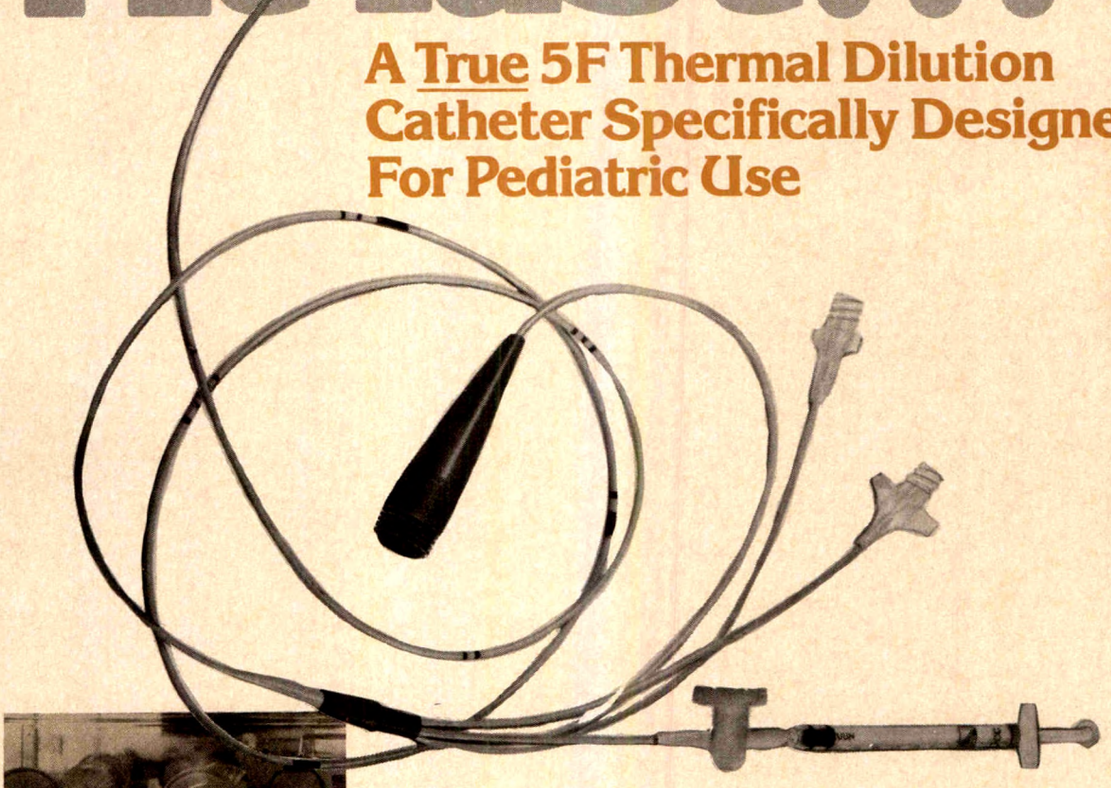
A True 5F Thermal Dilution Catheter Specifically Designed For Pediatric Use



The BALTHERM® Pediatric Thermal Dilution Catheter

- An accurately-designed, *true* 5F diameter catheter with a recessed balloon, enabling it to pass through a 5F introducer.
- Distal port will accommodate a .018 inch (.46mm) guide wire for catheter placement where guide wire assistance is required.
- Radiopaque
- Adaptable to virtually all leading computers

ELECATH BALTHERM PEDIATRIC CATHETER KIT #73-9045 for use with Edwards®, Hewlett-Packard®, Siemens® and Electro-Catheter COC5000 computers.

ELECATH BALTHERM PEDIATRIC CATHETER KIT #73-4045 for use with ALL Electro-Catheter Computers.

ELECATH BALTHERM PEDIATRIC KIT CONTAINS
- 5Fx75cm. catheter • 5F sheath over needle introducing assembly
- 1cc disposable syringe for balloon inflation

You can rely on your ELECATH representative to provide specialized service and recommendations on the complete ELECATH Family of cardiovascular products.

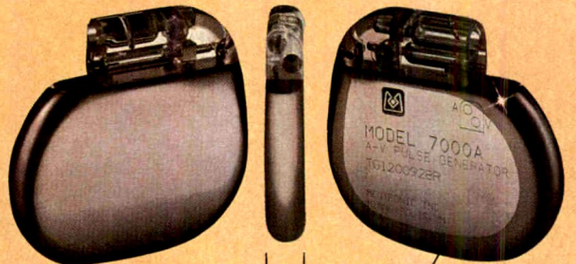
New VERSATRAX II

	340 ms.	A-V Sequential Pacing following a PVC…	235 ms.
THE FEATURE:	Atrial Refractory 340 ms. after a PVC…		Automatic Atrial Refractory adjusts to 235 ms. during A-V synchrony…
PATIENT BENEFIT:	To block sensing of retrograde when your patient needs it most	To restore synchrony	To track rapid atrial rates

Currently undergoing U.S. Clinical Evaluat

Keeps a heart beating like a heart.

The most physiologic pacemaker.



New Versatrax II Model 7000A is:

- **Automatic Atrial Refractory**
  The advanced physiological method of tracking the atrium and discriminating retrograde
- **Smallest**
  The most physiological size and shape available
- **Superior Sensing Performance**
  Medtronic's exclusive patented circuitry rejects most myopotentials
- **Plus... uniquely from Medtronic**
  - A-V Pacing System Analyzer—Model 5311
  - Endocardial screw-in leads—Models 6957/6957J
  - Follow-up choices—Cardiocare™/Teletrace™
  - Educational programs
  - Service options
  - Proven reliability

Versatrax™ II Model 7000A Universal A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

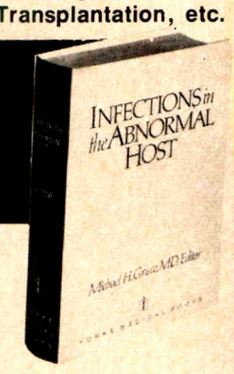
NOW AT YOUR FINGERTIPS...

the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which strike patients with:

Diabetes / Alcoholism / Cancer / Drug Addiction / Rheumatic Disease / Uremia / Pulmonary Disease / Hepatic Insufficiency / Allograft Transplantation, etc.

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

BASIC THERAPY FOR THE PREVENTION OF ANGINA PECTORIS*

Report from "Step-Care Therapy for Ischemic Heart Disease"
—a special symposium preceding the annual meeting
of the American College of Cardiology, April 24, 1982.

Synopsis of the Symposium

Step 1: Nitrates

Since nitrates both reduce myocardial oxygen demand and increase myocardial oxygen supply, their use is warranted as initial therapy for the control of angina pectoris. Dosage needs often vary significantly from patient to patient, and attention should be given to ensure that an adequate dosage level has been established.

Step 2: Nitrates and beta blockers

For angina refractory to maximum-dose nitrate therapy, the complementary actions of beta blockers and nitrates provide a rational therapeutic modality. At this point a beta blocker should be added to the nitrate regimen.

Step 3: Nitrates and calcium antagonists

Calcium antagonists have special usefulness in controlling cases where the myocardial oxygen supply is diminished by coronary vasospasm; their use in combination with nitrates is recommended if Step 2 therapy is unsatisfactory (or if the patient has variant or vasospastic angina).

Consensus of the Symposium

Nitrates are basic in step-care therapy for ischemic heart disease

Step 1
Stable or unstable angina: Nitrates

Step 2
If not controlled: Nitrates + beta blockers

Step 3
If still not controlled (or in variant angina): Nitrates + calcium antagonists

The basic antianginal agent in these basic dosage forms

In angina pectoris...

ISORDIL® (ISOSORBIDE DINITRATE)

is basic

*ISORDIL has been evaluated as probably effective when taken by the sublingual or chewable route and possibly effective when taken orally for this indication. See Brief Summary on following page.

Ives®

© 1982 Ives Laboratories Inc.

ISORDIL®
(ISOSORBIDE DINITRATE) IS BASIC

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

"Probably" effective: When taken by the sublingual or chewable route, Isordil Sublingual and Chewable Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks.

"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.
Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.
Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.
Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Consult direction circular before prescribing.

What is CARDIOLOGY 1982?

- The second in an annual series to be published in the SPRING each year
- A review of the year's newest and most important developments in cardiology — **665 papers**
- A multidisciplinary approach to clinical and applied research based on an exhaustive search of the year's literature
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

CARDIOLOGY:1982 is NOT

- A collection of unrelated reviews
- An abstracting service
- A rehash of materials readily available elsewhere

"It is more than merely a reference book, since it explains what to the average physician may be obscure....a treasure house of 1980 publications. It is highly recommended." Philip Reichert, M.D. New York State Journal of Medicine, September, 1981

"...recommend...to any reader interested in the literature of cardiology." Irwin R. Callen, M.D. JAMA, November, 1981

The Univentricular Heart: Combined 2-Dimensional–Pulsed Doppler (Duplex) Echocardiographic Evaluation

GEORGE S. BISSET, III, MD and STEPHEN S. HIRSCHFELD, MD

Two-dimensional echocardiographic-pulsed Doppler (2D-PD) evaluation was performed in 14 patients with a univentricular heart. Accurate information on ventricular structure, atrioventricular valve status, and great vessel anatomy and function was obtained. The characteristic morphologic features were verified in each case by angiography or autopsy, or both. In several patients, 2D-PD evaluation provided more accurate anatomic and functional information than did cardiac angiography in standard views, particularly with regard to atrioventricular valve function. Four children with pulmonary atresia and 4 with pulmonary stenosis were identified prospectively. No patient had 2D-PD evidence of aortic obstruction. Four children had typical 2D-PD patterns consistent with atrioventricular valve regurgitation. Thus, 2D echocardiography coupled with a range-gated Doppler system will improve recognition of patients with a univentricular heart and permit thorough evaluation of specific anatomic details.

With the introduction of improved surgical procedures in patients with a univentricular heart, accurate preoperative assessment has become essential. Anatomically and morphologically, these children may be difficult to evaluate, particularly in the neonatal period. Complex great vessel positions, the presence or absence of pulmonary or aortic stenosis, or both, and the contribution of a patent ductus arteriosus need to be recognized before planning long-term medical management. In the mid-1970s, several reports discussed M-mode echocardiographic features of the univentricular heart.[1–5] However, adequate surgical planning could not be undertaken on the basis of M-mode echocardiography alone.

Recently, 2-dimensional (2D) or cross-sectional echocardiographic techniques have provided more anatomic information on patients with univentricular heart,[6–8] but little functional data. More recently, 2D or cross-sectional echocardiographic techniques have been combined with range-gated pulsed Doppler (PD) to obtain specific anatomic and hemodynamic information.[9,10] Ventricular and atrial structure, atrioventricular (AV) valve connections, and great vessel relations have been visualized with use of 2D techniques.[6,11,12] With PD, additional information can be gained on pulmonary and aortic flow patterns,[13,14] AV valve competence,[15,16] and patterns of shunts.[17–19] No reports on the use of PD techniques in patients with univentricular heart have appeared.

The present report is a combined 2D echocardiographic-pulsed Doppler evaluation of 14 patients with a univentricular heart. The group includes all those patients whose heart demonstrated absence of the ventricular septum, as defined by Anderson et al.[20,21] Each patient underwent cardiac catheterization with selective angiography. Investigation was undertaken to evaluate the ability of the 2D-PD system to predict accurate information on AV valve structure and function, ventricular structure, and great vessel positions and flow patterns in children with a univentricular heart.

Definitions and Terms

Functional single ventricle-univentricular heart (terms used interchangeably): The definition of single ventricle is controversial.[21–23] We have chosen to accept the interpretation of Anderson et al,[20] who describe the univentricular heart as one in which the posterior ventricular septum is absent. Atresia of an AV valve, common AV valve, and straddling AV valve are included in this definition. These patients may or may not have ventricular outflow chambers.

Outflow chamber: This is a small infundibular chamber that communicates with the larger, main ventricle and is partially separated from it by the bulboventricular ridge, rather than the true ventricular

From the Tulane Medical Center and The Department of Pediatrics, Tulane University School of Medicine, New Orleans, Louisiana. Manuscript received April 12, 1982; revised manuscript received July 8, 1982, accepted July 9, 1982.

septum. This outflow chamber may not entirely encompass an AV valve anulus and may be in a noninverted (rightward) or inverted (leftward) position.

Atrioventricular valves: The AV valves are described as right-sided or left-sided, the right being anterior and the left being posterior. A common AV valve is defined as one that is single and midline, without commitment to the right or left.

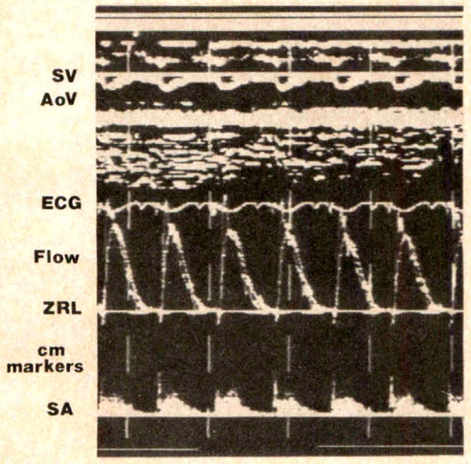

FIGURE 1. Standard display of pulsed Doppler echocardiographic tracing recorded at the level of the aortic valve (AoV). At the top is a compact M-mode echocardiogram. The sample volume (SV) is positioned in the aortic root. Below the M-mode tracing is an electrocardiographic rhythm strip (ECG). The spectral flow velocity is demonstrated as a series of dots arranged (in this example) in a linear pattern, indicative of laminar flow. Flow directed toward the transducer is indicated by deflection above the zero reference line (ZRL). The Doppler signal amplitude (SA) indicates the strength of the flow signal detected by the spectral processor. This tracing demonstrates normal, nonturbulent, aortic flow. Cm markers = 1 cm markers; flow = spectral velocity flow patterns.

Great vessel relationships: The vessels were defined as normally positioned, D-transposed, or L-transposed. The prefixes D and L refer only to the relative rightward or leftward positions of the aorta and provide little valuable morphologic data.

Methods

Fourteen patients, 6 boys and 8 girls, with presumed single ventricle underwent 2D echocardiography and PD analysis. Their ages were 1 day to 19 years (mean 5 years), and 7 (50%) were less than 6 months of age.

In each patient the diagnosis of single ventricle was established at cardiac catheterization. Seven patients underwent ultrasound examination before angiography. Of the remaining 6 patients, 2 were catheterized elsewhere and angiograms were not viewed before echocardiographic study. The other 4 patients underwent cardiac catheterization at this institution several years before the noninvasive studies. In 2 patients, autopsy results confirmed the cardiac diagnosis.

Ultrasound examinations were performed with the ATL Mark V System (Advanced Technology Laboratory, Bellevue, Washington), a self-contained echocardiography/Doppler duplex ultrasound system that permits sector-type, real-time visualization of cardiac images and frozen-frame evaluation of blood flow characteristics on the image, using PD techniques. We used a 5 MHz stationary rotor scan head with a receiver frequency response of 1 to 8 MHz broadband. Spectral and audio Doppler signals provided flow velocity information from a 2 by 4 mm Doppler sample volume. With range gating, this Doppler sample volume could be positioned anywhere along a continuously variable M-mode line, with a maximal depth of 9 cm. An M/Q display of the Doppler spectrum was recorded from the echocardiographic oscilloscope (315A Video Display) (Fig. 1). In the upper portion of the display the M-mode echocardiogram is visualized, with a superimposed line indicating the Doppler sample volume location. Below this display is the simultaneously recorded electrocardiogram. The lower half of the format reveals the spectral flow velocity pattern and the Doppler signal amplitude. Flow toward the transducer is represented by dis-

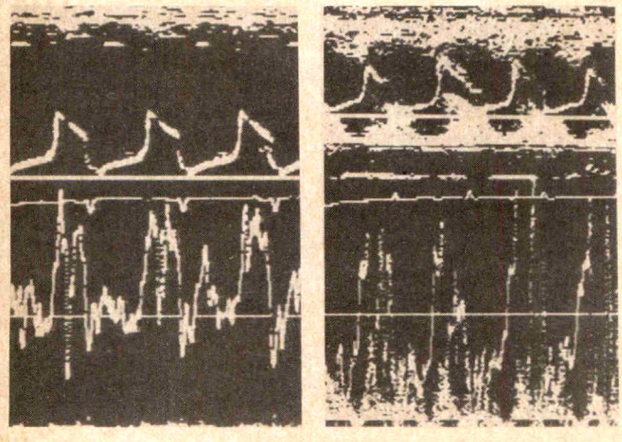

FIGURE 2. Atrioventricular valve competence as demonstrated in an apical view. A 2D apical view of the heart was used with localization of the Doppler sample volume within the mitral anulus. The same view was used to detect tricuspid valve insufficiency. **Left,** normal mitral flow is indicated by nonturbulent flow directed toward the transducer during ventricular diastole. Little flow is detected during ventricular systole. **Right,** mitral insufficiency is demonstrated by noting turbulent flow directed away from the transducer during ventricular systole.

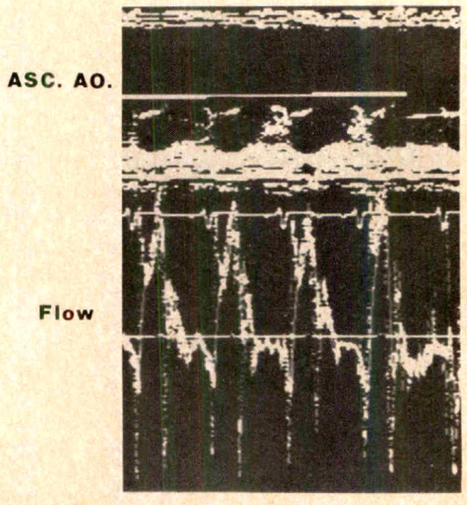

FIGURE 3. Demonstration of Doppler flow in the aortic root. Normal aortic flow pattern from suprasternal notch view. Laminar flow is directed toward the transducer during systole. ASC. AO = ascending aorta.

placement of the histogram above the baseline, and flow away from the transducer by displacement below the baseline. Turbulent flow is demonstrated by dispersion of the time interval histogram, whereas coherence of the pattern suggests laminar flow.

The patients were examined in the supine position with the transducer initially in the third or fourth intercostal spaces along the left sternal border. Long- and short-axis views of the ventricles and great vessels were obtained. Acoustic windows in the apical, subxiphoid, and suprasternal notch areas were also used in each patient to visualize various structures. The method for obtaining these views was previously described.[6] PD examinations were attempted in positions in which the flow was least perpendicular to the Doppler sample volume, so as to maximize the opportunity of detecting the optimal Doppler signal. Evaluation of the histograms was qualitative, as no attempt was made to quantitate flow volumes.

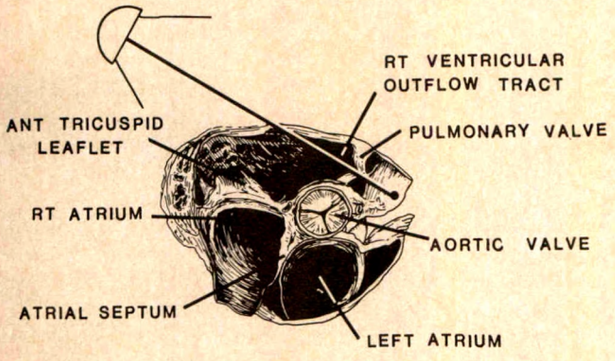

FIGURE 4. Placement of the Doppler sample volume (**black dot**) in the main pulmonary artery. The short-axis view maximizes the ability to detect laminar or turbulent flow. ANT = anterior; RT = right.

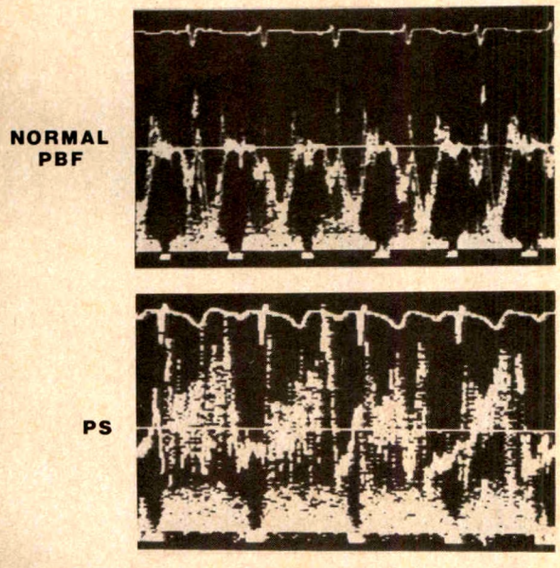

FIGURE 5. Top, laminar flow pattern demonstrated in the main pulmonary artery in a patient with catheterization-proven normal pulmonary blood flow (PBF). **Bottom,** the time interval histogram of a patient with pulmonary stenosis (PS) reveals a widely dispersed dot pattern consistent with turbulent systolic flow.

To evaluate AV valve status, an apical 4-chamber view was used (Fig. 2). The Doppler sample volume was positioned in the left atrium (or common atrium) and subsequently in the right atrium just proximal to the AV valve. This position approximated the center of the valve ring. The Doppler recordings were initially performed in this position and then the Doppler sample volume was moved more proximally and from side-to-side in the atrium in attempts to localize a regurgitant stream. Any turbulent flow directed below the baseline during systole was defined as AV valve insufficiency.

PD examinations also were performed to evaluate flow patterns in the aortic and pulmonary outflow tracts (Fig. 3 and 4). Suprasternal notch and long- and short-axis views were optimal for performance of these studies. The Doppler sample volume was initially positioned just distal to the valve and then advanced through the valve to a more proximal position in the outflow tract. In patients with unobstructed pulmonary blood flow, typical laminar histograms were obtained and were associated with a smooth audio signal (Fig. 5). Patients with aortic or pulmonary stenosis demonstrated normal flow patterns proximal to the obstruction and turbulent flow, with a rough audio signal distal to the obstruction. Children with patent ductus arteriosus had Doppler continuous flow patterns in the pulmonary trunk. If pulmonary atresia was present, no flow was demonstrated proximal to the pulmonary valve, and ductal or surgically created shunt flow patterns were visualized distal to the valve. This pattern has been described previously by Korfhagen et al.[24]

Results

Ventricular structure: In each of the 14 patients, the 2D-PD examination was accurate in predicting ventricular structure (Table I). Nine patients had findings consistent with single ventricle of the left ventricular type, that is, the outflow chamber, as identified by the bulboventricular ridge, was directed toward the right and anterior.[25] In 2 patients the outflow chamber was left-sided and anterior, suggesting ventricular inversion. The great vessels were L-positioned, lending further credence to the diagnosis of inversion. The remaining patient with ventricular inversion demonstrated dextrocardia with a large, smooth-walled, right-sided chamber and a small, anterior, leftward

AV = atrioventricular; SV = single ventricle.

outflow chamber giving rise to the aorta. In the 2 patients with undifferentiated single ventricles, no outflow chamber was identified, that is, no bulboventricular ridge could be identified. Angiography confirmed this finding.

Atrioventricular valves: Six patients had 2 AV valves demonstrated. In every case, the right-sided valve appeared to be approximately one-fifth to one-third the size of the left-sided valve (Fig. 6). One child with a straddling, small dysplastic right-sided AV valve demonstrated regurgitation of the valve on Doppler examination.

Two children had thickened, ultrasound-dense membranes in regions where normal right-sided AV valves were developmentally expected. Another child had the same plate-like density on the left side (Fig. 7). No patient had AV valve regurgitation.

Of the 5 children with single, uncommitted AV valves, the 3 with outflow chambers had evidence of AV valve regurgitation on Doppler examination, which was confirmed at cardiac catheterization. At autopsy, 1 of these 3 had a rudimentary right ventricular outflow tract and a large dysplastic AV valve typical of an endocardial cushion defect.

Great vessel relationships and flow patterns: Five patients in the group had a normal "ball and sausage"[11] appearance of the great vessels on a short-axis view at the cardiac base. Five had D-transposed great vessels and 4 had L-positioned arteries.

No patient had Doppler evidence of aortic outflow tract obstruction. This fact was verified in 10 of the 14 patients at the time of cardiac catheterization. Pullback left ventricle-to-aorta pressures or simultaneous pressures in the left ventricle and aorta, or both, were not obtained in the remaining 4 patients.

Four children had laminar flow patterns in the pulmonary trunk. Absence of histogram dispersal in these patients indicated unobstructed pulmonary blood flow. Four patients had turbulent systolic flow patterns in the pulmonary artery distal to the valve. Two had smooth patterns proximal to the valve, suggesting that the area of stenosis was localized to the pulmonary valve. The other 2 had turbulent patterns proximal and distal to the valve. In these children, it was difficult to determine whether the obstruction was localized to the infundibular area alone or whether there was additional valvular stenosis.

Four children had absent flow in the infundibular region just proximal to the valve. When the Doppler sample volume was advanced across the valve, a typical Doppler signal of continuous flow was noted, representing either a patent ductus arteriosus or a surgically created shunt (Fig. 8). Each child had a confirmed angiographic diagnosis of pulmonary atresia. The remaining 2 patients had turbulent flow in the pulmonary trunk just distal to the band. The band could be visualized adequately in both cases by 2D echocardiography.

Interatrial septal structure: Subxiphoid 2D-PD was used to view the atrial septum and to evaluate flow patterns. Three patients were believed to have an intact atrial septum. One of these 3 patients had a patent foramen ovale at cardiac catheterization.

Five children had 2D echocardiographic evidence of a dilated patent foramen ovale versus secundum-type atrial septal defect. The ability to distinguish the 2 with confidence was poor. In each patient, a localized gap was noted in the midseptal region. A septum primum flap was not identified in 4 of the 5 patients. In none of these 4 was a distinct septal bulge identified, thereby making the diagnosis of an actual absence of tissue, that is, atrial septal defect, most likely.

In the single patient with redundant primum tissue, there was no septal bulging. Therefore, it was difficult to determine whether there was restriction to flow (as

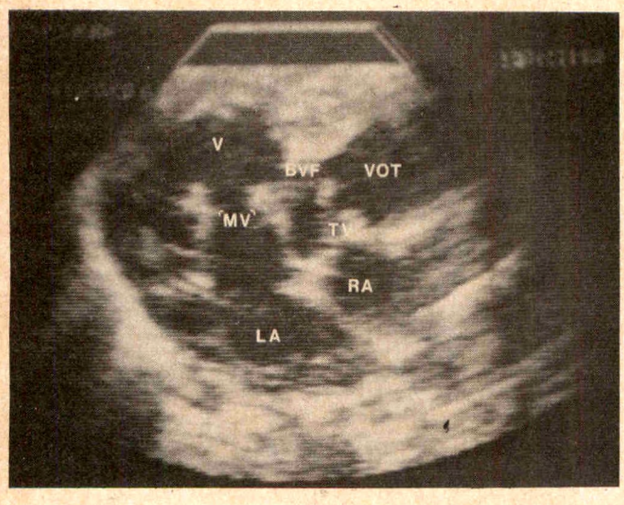

FIGURE 6. A slightly angulated long-axis view in a patient with a single ventricle and 2 AV valves. The tricuspid valve (TV) in this patient was much smaller than the mitral valve (MV). BVF = bulboventricular flange; LA = left atrium; RA = right atrium; V = ventricle; VOT = ventricular outflow tract.

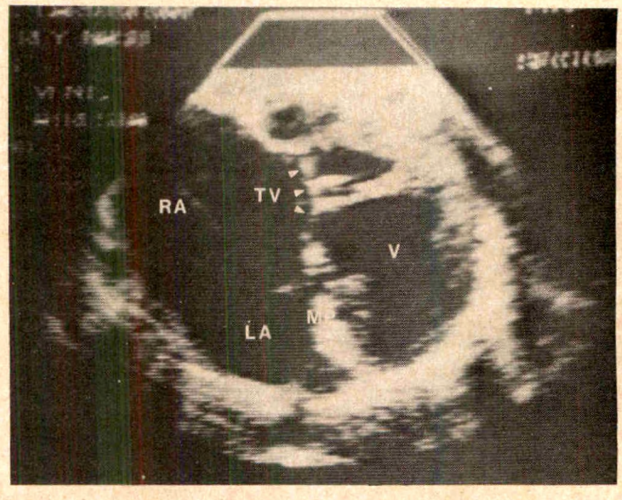

FIGURE 7. Subxiphoid view in a patient with mitral atresia. MP denotes the atretic mitral plate. The **small arrows** indicate the tricuspid valve (TV) anulus. A small remnant of atrial septum divides the 2 atria inferiorly. LA = left atrium; RA = right atrium; V = ventricle.

might be expected with a stretched patent foramen ovale) or a nonrestrictive defect. Four patients had an isolated defect low in the septum, consistent with an ostium primum defect. One patient had multiple (ostium primum and secundum) defects and the remaining patient had total absence of the atrial septum.

Discussion

Two-dimensional–pulsed Doppler echocardiography has greatly enhanced the ability to define the anatomic and hemodynamic characteristics of patients with a univentricular heart. In our 14 patients, an excellent correlation was found between 2D-PD evaluation and angiographic, surgical, and autopsy observations. Our report attempts to noninvasively delineate features of patients with 1 functional ventricular chamber. We hope this concept is useful to the clinician.[22]

Ventricular structure was readily appreciated by the 2D echocardiographic technique. In every patient the outflow chamber, or the absence thereof, was identified. In several patients the trabecular patterns of the ventricles also could be clarified.

Identification of the AV valve orifices also was accurate, which is especially important because angiography may occasionally prove unsuccessful in adequately visualizing these valves. In many cases, this angiographic identification depends on negative contrast effects superimposed on a dye-filled ventricle. This technique may not be very accurate, especially in the presence of small AV valves.

Another problem that may occasionally be masked during catheterization is AV valve regurgitation. Quantification by ventriculography has several inherent problems.[26] Unless proper angiographic angulation is obtained, mild degrees of regurgitation may be missed. By comparison, the Doppler sample volume is readily positioned in the valve orifices to look for mitral or tricuspid regurgitation, or both. This ability to detect AV valve regurgitation may be particularly important in those patients undergoing Fontan-type procedures in which an unrecognized inherently damaged left-sided valve may create significant management problems.[27]

The diagnosis of tricuspid and mitral atresia is readily recognized. "Plate-like" densities can be visualized where normal valves are expected.

As Henry et al[11] aptly noted, the 2D echocardiogram is extremely useful in delineating great vessel relationships. In our patients, the only diagnostic obstacles were in some patients with pulmonary atresia. The short-axis view at the level of the great vessels could readily identify the large aorta; however, it was sometimes more difficult to visualize the atretic pulmonary valve, particularly when the vessels were D-transposed. When the vessels were normally related, there was little difficulty in visualizing the pulmonary trunk distally as it wrapped around the aorta.

The range-gated PD system was particularly useful in evaluating great vessel hemodynamic characteristics. Long- and short-axis, subxiphoid, and suprasternal notch views were used in freeze-frame positioning of the Doppler sample volume. Initial placement was distal to the valve, with continuous recording of the histogram and audio signals as the Doppler sample volume was moved through the valve to a more proximal position in the outflow tract.

In every patient, the Doppler sample volume sweep of the aorta demonstrated laminar or minimally disturbed patterns distal and proximal to the valve. No patient had aortic obstruction on cardiac catheterization, thereby making the ultrasound evaluation sensitive.

Two-dimensional–pulsed Doppler echocardiography was also useful in evaluating the status of the subpulmonary region and pulmonary trunk. Flow patterns were classified by histogram dispersal. Typical high flow patterns, that is, large amplitude spikes with little scatter, were noted in each patient with catheterization-proven unobstructed pulmonary blood flow. Although high flow occasionally resulted in slight broadening of the band pattern, the spectral band in each of these children was more typical of nonturbulent flow (broadband less than 1 cm in amplitude).[28] With these criteria, minimal degrees of valve obstruction may be missed, although these gradients are probably of little clinical significance.

Pulmonary stenosis typically produces a widely dispersed dot pattern during systole, representing turbulence. Initial placement of the Doppler sample volume in the main pulmonary artery accurately demonstrated turbulence in each patient with pulmonary stenosis. In patients with pulmonary arterial bands, the turbulence occurred just distal to the band. As the Doppler sample volume was moved into the outflow tract, the most proximal area of obstruction was identified. When infundibular pulmonary stenosis was present, it was difficult to detect additional valvular stenosis, as turbulence persisted well into the pulmonary trunk.

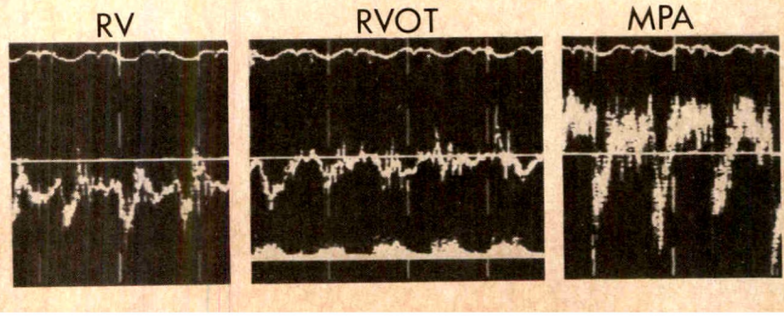

FIGURE 8. Doppler sweep of the right ventricular outflow tract in a patient with single ventricle and pulmonary atresia. A short-axis view was used. The time interval histogram in the body of the right ventricle (RV) illustrates nonturbulent flow directed away from the transducer during systole. When the sample volume is repositioned in the right ventricular outflow tract (RVOT), the amplitude of flow is greatly diminished. Once the sample volume is advanced distal to the atretic pulmonary valve, a widely dispersed dot pattern is demonstrated, associated with a rough continuous audio signal. This pattern is consistent with turbulent flow through a patent ductus arteriosus. MPA = main pulmonary artery.

In the children with pulmonary atresia and ductal- or shunt-dependent pulmonary blood flow, another typical pattern was identified. A continuous flow pattern accompanied by a rough continuous audio signal was typical of the lesion proved by catheterization. This pattern of ductal flow was noted and specific even in patients with high pulmonary blood flow.

Atrial septal morphology was accurately identified in most patients using 2D techniques. In several, however, it was difficult to absolutely distinguish between a secundum type atrial septal defect and a dilated patent foramen ovale. Although each demonstrated a mid-septal gap, absence of a clearly visible septum primum flap (negative echocardiographic finding) was not believed to be synonymous with absence of tissue and, hence, a true atrial septal defect. However, because there was no septal bulging, an atrial septal defect, rather than stretching of a patent foramen ovale, was more likely responsible for the septal dropout. Inability to distinguish the 2 with certainty did not appear clinically significant in patients with a single ventricle and 2 AV valves. In 2 of the 3 patients with mitral or tricuspid atresia, the inability to distinguish the difference has also been clinically unimportant. However, in the remaining patient with tricuspid atresia, the small size of the defect, the presence of primum flap tissue, and the appearance of systemic venous congestion prompted us to recatheterize the patient to be sure the defect was nonrestrictive. The defect proved hemodynamically nonrestrictive.

Although PD evaluation of the atrial septum was carried out in this subgroup of patients, the results were of little value in assisting with clinical management of the patient. The anatomic definition by 2D visualization seemed more important.

The use of 2D-PD has significantly broadened noninvasive expertise. Previously, it was difficult by echocardiography alone to distinguish between patients with single ventricles and those with large ventricular septal defects, complete AV canals, straddling tricuspid valves, and corrected transposition of the great vessels with ventricular septal defects.[3] These conditions can now be readily differentiated and additional information on hemodynamic function can be obtained. Children with semilunar valvular stenosis or AV valve regurgitation or stenosis, or both, can be recognized.

The combination of real-time and 2D imaging with a range-gated PD system represents a very useful tool in pediatric cardiology. This technique provides information that complements the remainder of the noninvasive work-up. The sensitivity and relative specificity of this "duplex" system may provide information that may not be obtainable at cardiac catheterization. Certainly, in the sick newborn in whom invasive procedures carry a high risk, this technique could be used to arrive at a specific diagnosis, so that palliative surgery could be performed. This technique may not totally supplant cardiac catheterization in these complex patients with a univentricular heart; however, angiography may frequently be avoided. Certainly this noninvasive procedure will greatly aid in planning the invasive study and may permit abbreviated studies to be undertaken.

Prognostic Value of Left Ventricular Size Measured By Echocardiography in Infants With Total Anomalous Pulmonary Venous Drainage

CARLOS OLIVEIRA LIMA, MD, LILLIAM M. VALDES-CRUZ, MD, HUGH D. ALLEN, MD, SUZANA HOROWITZ, DAVID J. SAHN, MD, STANLEY J. GOLDBERG, MD, JESUS VARGAS BARRON, MD, and EHUD GRENADIER, MD

Left ventricular size may be a determinant of survival in infants with total anomalous pulmonary venous drainage. Right and left ventricular size were measured by M-mode and 2-dimensional (2-D) echocardiography in 13 patients aged 1 day to 4 months (mean weight 4.3 ± 0.42 kg [standard error of the estimate]) who underwent surgery before age 4 months because of severe cyanosis or cardiac failure. Seven patients had venous drainage to a vertical vein, 4 had drainage to the right atrium, and 2 had drainage to the inferior vena cava. Patients were divided into 2 groups: survivors (Group A, n = 8) and nonsurvivors (Group B, n = 5). Death was not statistically related to pulmonary artery pressure, pulmonary venous obstruction, age, or weight at the time of surgery. Right and left ventricular sizes at end-diastole measured from M-mode traces and 2-D echocardiographic 4-chamber views were compared with those from 15 weight-matched control infants. On M-mode and 2-D echocardiography, nonsurvivors had significantly larger right ventricles and smaller left ventricular dimensions than did either control subjects or surviving patients with total anomalous pulmonary venous drainage. The ratio of right to left ventricular size on M-mode and 2-D echocardiography also differed among the 3 infant groups ($p < 0.001$). The ratio of right to left ventricular size differentiated nonsurvivors from survivors and control subjects. Postmortem examinations available in 4 of the 5 nonsurvivors demonstrated that the ratio of right to left ventricular size in the specimens closely agreed with the 2-D echocardiographic ratios. Our study agrees with the impression of other investigators that left ventricular size may be a determinant of survival after repair of total anomalous pulmonary venous drainage.

Total anomalous pulmonary venous drainage (TAPVD) is an uncommon form of congenital cardiac disease in which all pulmonary veins drain to the right atrium, either directly (30%) or through supracardiac (47%) or infracardiac (18%) channels.[1] Clinical manifestations vary but surgical repair is required, with mortality rates ranging from 16 to 30%.[2–6] One factor influencing operative mortality is left ventricular size.[7–9] In 13 patients who underwent early operative repair of TAPVD, we measured right and left ventricular size, as determined by echocardiography, to evaluate its potential use in predicting survival.

Methods

Patient population: The patient population consisted of 13 infants aged 1 day to 4 months, with a mean weight of 4.3 ± 0.42 kg (standard error of the estimate [SEE]), with a diagnosis of TAPVD confirmed by cardiac catheterization and angiography. Eleven patients were studied at Arizona Health Sciences Center; 2 were studied at Green Lane Hospital, Auckland, New Zealand, during a sabbatical leave of 1 of the authors (DJS). At catheterization, right and left ventricular pressures were measured and their ratios (RV/LV) calculated in 11 of 13 patients; all underwent balloon atrial septostomy during the initial diagnostic study. Oxygen saturation ranged from 51 to 82% and pH was >7.3 in all patients immediately preoperatively. Seven patients had drainage to the superior vena cava through a vertical vein, 4 had drainage to the right atrium, 3 of them to the coronary sinus, and 2 had infradia-

phragmatic drainage with obstruction. All had operative repair before 4 months of age because of cyanosis, unrelenting cardiac failure, severe failure to thrive, or all 3. Patients were divided into 2 groups: Group A, survivors (n = 8); and Group B, nonsurvivors (n = 5). All infants except 2 survivors operated on in New Zealand were operated on by the same surgeon with similar surgical technique, cardioplegic solution, and comparable postoperative care. The cause of death in 1 was uncontrollable hemorrhage, through the anastomosis in a very small left atrium.[10] The other 4 died in a low cardiac output state which could not be reversed either in the operating room or within the first 12 hours postoperatively.

Patients underwent M-mode and 2-dimensional (2-D) echocardiographic examination before surgical repair. Three of 8 survivors were studied serially over a 4 to 6 week period before repair. Fifteen weight-matched normal infants served as the controls.

M-mode studies: M-mode echocardiograms were performed with a Smith Kline Ekoline 20A and a Honeywell 1856 strip chart recorder. Simultaneous lead II electrocardiograms were recorded for timing purposes. Right and left ventricular and left atrial cavity size was measured by the leading edge method according to recommendations of the Committee on M-Mode Standardization of the American Society of Echocardiography[11] with a computerized clinical graphics analyzer (Numonics®).

Two-dimensional studies: Two-dimensional echocardiographic studies were conducted using a 2.4 MHz, electronically focused, phased array device (Toshiba SSH 10A) with a specially damped pediatric transducer (PS 24A-2), a 30° or 82° 5-MHz mechanical sector scanner (Smith Kline Ekosector I) or a prototype 3.5 MHz, dynamically focused, phased array instrument designed and built at the General Electric Research and Development Center, Schenectady, New York.

Studies were recorded on videotapes that were played in slow motion for frame-by-frame analysis. Left and right ventricles were measured from the inner edge of the left or right side of the septum to the inner edge of the corresponding free wall endocardial surface. To maximize ventricular size, measurements were taken at end-diastole at a level just inferior to the atrioventricular valves from an apical 4-chamber plane image[12] (Fig. 1). The left atrium was measured from a parasternal long-axis view at end-systole with the aorta at its most forward point, using the leading edge technique at the level of the aortic valve. The ratio of right to left ventricular size (RV/LV) was calculated from M-mode and 2-D measurements.

Autopsy measurements: Postmortem specimens were available in 4 of 5 nonsurviving infants. The hearts had been fixed in formaldehyde. Right and left ventricular sizes were measured from inner endocardial surfaces using a 4-chamber plane equivalent to the 2-D echocardiographic view. The ratio of right to left ventricular size was calculated from the specimens. Only the ratios were used in data analysis for comparison to echocardiographic dimensions, because the absolute cardiac dimensions had been altered by fixation.

Repeatability of measurements: To determine repeatability, all echocardiographic and postmortem measurements were performed in duplicate, at separate sittings, by 1 inves-

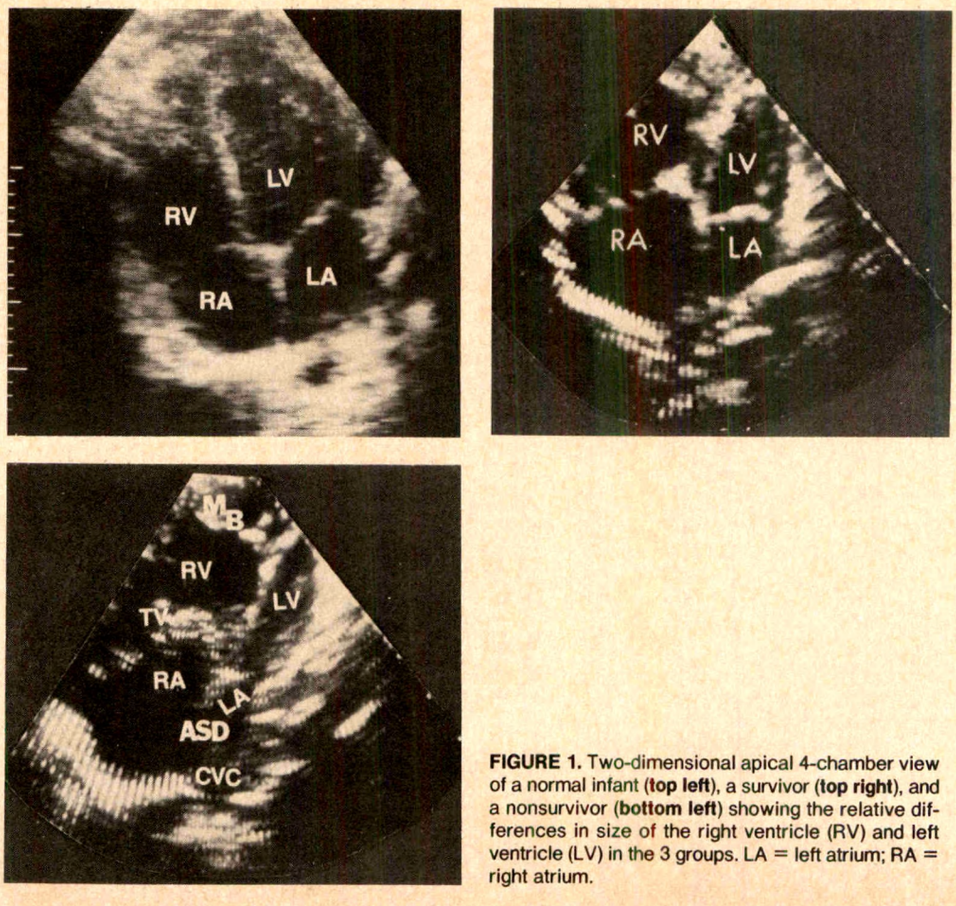

FIGURE 1. Two-dimensional apical 4-chamber view of a normal infant (**top left**), a survivor (**top right**), and a nonsurvivor (**bottom left**) showing the relative differences in size of the right ventricle (RV) and left ventricle (LV) in the 3 groups. LA = left atrium; RA = right atrium.

tigator. To test interobserver variability, all measurements were performed by 2 investigators who were unaware of each other's results, clinical outcome, or patient grouping.

Statistical analysis: Correlation coefficients were calculated to compare M-mode and 2-D results for right and left ventricular and left atrial sizes. Analysis of variance was used to detect differences among the 3 groups (control, survivors, and nonsurvivors) in weight, chamber size, and RV/LV ratios in both M-mode and 2-D views. A restricted least-significant difference comparison was then applied to compare intergroup differences.[13] Student's t test was calculated to compare age at time of surgery, oxygen saturation, and right and left ventricular pressure in surviving and nonsurviving patients. Ratios of RV/LV calculated from 2-D and postmortem data were also compared by the t test. The paired t test was used to analyze measurement repeatability and interobserver variability.

Results

Complete M-mode studies were performed on 10 of 13 infants and complete 2-D echocardiographic examinations were available in 12 of 13 patients. Nonrestrictive interatrial communications were found in all 12 patients on postcatheterization 2-D examination, confirming the adequacy of balloon atrial septostomy in all. Fifteen normal control subjects had acceptable M-mode and 2-D studies.

Clinical and echocardiographic results are summarized in Table I. The 3 groups were comparable with respect to weight. The ratio of right to left ventricular pressure available from catheterization data in 11 of 13 infants <1 month before operation ranged from 0.5 to 1.6 but was not statistically different between survivors and nonsurvivors. Furthermore, age, oxygen saturation, and acid-base balance at operation and sites of drainage of the pulmonary veins were similar in the 2 patient groups. Postmortem examination showed that the ratios of right to left ventricular dimensions in the anatomic specimens closely agreed with ratios derived from the 2-D echocardiographic images (Table I).

M-mode results: Analysis of variance demonstrated that right ventricular and left ventricular sizes were statistically different in the 3 groups ($p < 0.001$ and $p < 0.01$, respectively). Nonsurvivors as a group had smaller left ventricles and larger right ventricles than did either normal subjects or survivors. RV/LV ratios were significantly different in the 3 groups ($p < 0.001$). Control subjects had the smallest mean ratio (mean 0.6 ± 0.15 [standard deviation]), whereas nonsurvivors had the largest (mean 1.4 ± 0.03). All nonsurvivors exceeded a ratio of 1.3. Left atrial size was not statistically different among the 3 groups.

Two-dimensional echocardiographic results (Table I, Fig. 2): Right ventricular dimension was similar in both groups of patients with TAPVD and was larger than that in control subjects ($p < 0.05$). The left ventricle was smaller in nonsurvivors than in either control subjects or surviving infants with TAPVD ($p < 0.05$) (Fig. 1).

The RV/LV ratio best separated the 3 groups ($p < 0.001$): the ratio in control subjects (mean 0.6 ± 0.05) was significantly smaller than that in survivors (Group A) (mean = 1.1 ± 0.13, $p < 0.001$), who in turn had smaller ratios than the nonsurviving infants (mean 1.7 ± 0.29, $p < 0.01$). All nonsurviving infants had absolute ratios >1.4 (Fig. 2). Left atrial size was not significantly different among the 3 groups.

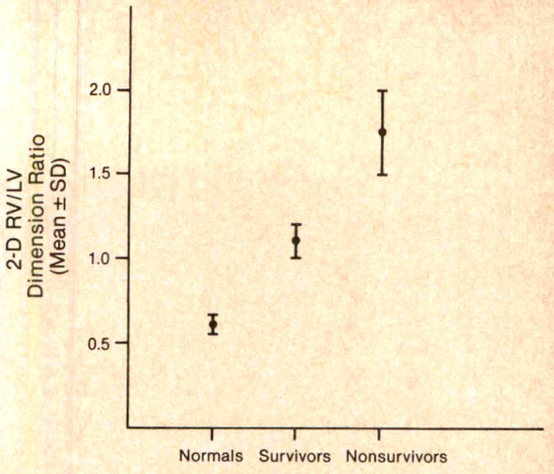

FIGURE 2. Ratio of right ventricular to left ventricular dimension (RV/LV) measured by 2-D echocardiography in normal children and patients with total anomalous pulmonary venous drainage. The RV/LV ratios statistically separated the 3 groups. SD = standard deviation.

Serial 2-D studies: Three patients studied serially belonged to the survivor group. Their RV/LV ratios were all <1.4 and remained so throughout the preoperative course without significant change over 4 to 6 weeks.

Correlation of M-mode and 2-D measurements: Weak but significant correlations existed between M-mode and 2-D measurements of the right ($r = 0.7$, SEE ±0.27, $p < 0.05$) and left ventricle ($r = 0.7 \pm 0.25$, $p < 0.05$). The M-mode echocardiogram usually underestimated ventricular size when compared with the 4-chamber apical plane. A strong correlation was found between M-mode and 2-D echocardiographic measurements of the left atrium ($r = 0.94 \pm 0.1$, $p < 0.001$).

Interobserver variability and errors of repeatability: Cavity measurements derived from M-mode and 2-D images as well as from postmortem specimens were both highly repeatable. The standard error of the mean testing repeatability was <5% when duplicate measurements on a given image or specimen were compared. Interobserver variability in measuring echocardiographic data and autopsy specimens was also <5%.

Discussion

In this study significant right ventricular enlargement and smaller than normal left ventricular cavity dimensions were found in infants with TAPVD. These findings were most pronounced in nonsurviving patients in whom ratios of RV/LV size were statistically higher than those in surviving infants.

Our previous studies[14] and those of others[15] demonstrated that some size differences apparent on the echocardiogram can represent a change in left ventricular shape caused by septal indentation into the left

Age = age at operation; Angio Obstr = evidence of pulmonary venous obstruction by angiography; CS = coronary sinus; INFRA = infradiaphragmatic drainage; LA = left atrial dimensions; LV = left ventricular dimensions; O_2 Sat = arterial oxygen saturation at operation; RA = right atrium; RV = right ventricular dimensions; RV/LV = ratio of right to left ventricular size; SVC = superior vena cava; Site = site of drainage of pulmonary veins; 2-D data = results of 2-D echocardiograms; Wt = weight of patient (kg) at operation.

ventricle as a result of volume and pressure overload of the right ventricle. In this study, cavity measurements were taken only at end-diastole from a 4-chamber apical plane just below the atrioventricular valves in order to maximize chamber dimensions and minimize the possible influence of septal indentation. Agreement between postmortem and echocardiographic RV/LV ratios confirms the relative difference in ventricular dimensions. Subcostal views were not used to measure chamber size because they usually do not permit adequate visualization of the entire right ventricle.

Although M-mode measurements usually underestimated cavity sizes compared with 2-D measurements, RV/LV ratios appeared to cancel the measuring error. The resulting M-mode and 2-D ratios were comparable and equally predictive of survival. All 2-D measurements also tend to underestimate the actual size of imaged structures because of lateral resolution distortion inherent in the method. Nonetheless, using the ratio of the 2-D cavity measurements obtained in the lateral direction from the 4-chamber view negates any differences caused by absolute lateral resolution characteristics of the 2-D echocardiographic systems used in the study, thereby allowing comparison of the data.

Factors influencing mortality in TAPVD are numerous. Although 2 infants with subdiaphragmatic drainage operated on at ages 1 and 2 days both died after surgery, in our group of patients, age at operation,[16–18] oxygen saturation, acid-base balance, site of drainage, or presence of obstruction[16,17] did not specifically differentiate survivors from nonsurvivors. The ratio of RV/LV pressure has been used to suggest the presence of pulmonary venous obstruction and predict survival. Although in our patient group nonsurvivors had higher pressure ratios than did survivors, they were not statistically different, perhaps because of the small number of patients.

Four of the 5 nonsurvivors died in irreversibly low cardiac output. This finding suggests the possibility of inadequate left ventricular size, that is, a left ventricle incapable of sustaining systemic cardiac output in the immediate postoperative period. Similar suggestions have been made in angiographic, surgical, and pathologic studies by others.[7,9,15]

Although cardiac catheterization and selective angiography continue to be crucial in defining hemodynamics and confirming the site of anatomic drainage, serial study of the interrelations between right and left ventricular size in infants with TAPVD is of pertinent clinical interest. Right and left ventricular relations remained stable in our infants studied serially over 4 to 6 weeks; all of these infants survived. Infants with echocardiographic evidence of a rapid increase in right ventricular size or in RV/LV ratio should be considered for prompt operative repair, because these findings imply obstruction to pulmonary venous drainage at either the common pulmonary vein or the atrial septum.

We conclude that serial assessment of chamber size, which can only be performed noninvasively, should be of significant use in studying the course and estimating the prognosis of infants with TAPVD.

Hypertrophic Obstructive Cardiomyopathy: Ten- to 21-Year Follow-Up After Partial Septal Myectomy

MARGARET M. BEAHRS, MD, ABDUL J. TAJIK, MD, JAMES B. SEWARD, MD, EMILIO R. GIULIANI, MD, and DWIGHT C. McGOON, MD

This study reviews the outcome in 36 consecutive patients who survived partial septal myectomy for hypertrophic obstructive cardiomyopathy operated on between 1960 and 1972. All patients were followed up until death or until June 1981 (mean 13.4 years). Of the 26 survivors, 17 had been more than mildly symptomatic preoperatively, but only 1 remained so postoperatively. The operation was effective in relieving the obstruction (peak systolic pressure gradient reduced from 79 to 8 mm Hg [$p < 0.001$]), and mitral regurgitation was relieved. No survivor's symptoms worsened, but 10 died late—4 suddenly, 5 from congestive heart failure, and 1 from a malignancy. The 10-year survival rate was 77%. No correlation with outcome was found with respect to age, surgical approach, preoperative functional class, pressure gradient, left ventricular end-diastolic pressure, or presence of atrial fibrillation, but atrial fibrillation occurring late postoperatively (12 patients) was associated with an increased frequency of late death (7 of 10 late deaths) or continuing New York Heart Association functional class III status. Early or late postoperative complete heart block occurred in 1 patient each. Thus, these results suggest a favorable effect of operation and support continued surgical intervention for appropriate patients.

The management of patients with hypertrophic obstructive cardiomyopathy has remained a challenge over the past 2 decades since its description in 1957.[1] In the symptomatic patient, efforts have been directed toward relief of symptoms either by beta-adrenergic blocking drugs or by operation (septal myectomy). Propranolol has provided symptomatic relief in 80 to 90% of patients treated at our institution and elsewhere,[2,3] although prevention of sudden death and increase in survival over that of the natural history of the disease remain unproved.[4,5] Recent therapeutic trials with verapamil[6,7] and vigorous antiarrhythmic regimens[8] appear promising.

In patients who do not respond to medical therapy, surgery has played a major role. The techniques of partial septal myotomy and myectomy,[2,9–20] mitral valve replacement,[21,22] construction of a left ventricular outflow tract with a valved conduit,[23] and aortoventriculoplasty[24] have been reported, and their relative merits and disadvantages have been debated.[25,26] Partial septal myectomy has been the surgical procedure of choice at the Mayo Clinic, having been used from 1959 to 1980 in 80 patients with hypertrophic obstructive cardiomyopathy. This report presents extended long-term follow-up of the operative survivors of the first 40 patients (1959 through 1972) with specific emphasis on the late postoperative clinical course, complications, and modes of death. The initial Mayo Clinic experience with surgical treatment[20,27] and early surgical follow-up of this same group of patients were reported previously.[28]

Methods

In the early surgical follow-up of this group of 40 patients, there were 4 operative deaths (death during operative hospitalization or within 30 days of operation), for an operative mortality of 10%, the details of which were previously reported.[28] The patients constituting the present study group are the 36 surgical survivors, who were followed up to June 1981 or until death. No patients was lost to follow-up, the duration of which ranged from 2 to 21 years (mean 13). Follow-up information was obtained for all patients from examinations at the Mayo Clinic or from physician telephone interviews and correspondence with the patients, relatives, and referring physicians.

The study group of 36 included 28 adults and 8 children (22 male and 14 female). The mean age at operation was 31 years (range 16 months to 63 years). All patients had clinical and hemodynamic documentation of hypertrophic obstructive

TABLE I Symptoms Preoperatively and at Long-Term Follow-Up in 36 Patients

	Preoperatively		Postoperatively	
Symptom	n	%	n	%
Dyspnea	27	75	18	50
Angina	24	67	12	33
Near-syncope	11	31	5	14
Syncope	8	22	3	8

cardiomyopathy.[28] Only 7 patients took propranolol preoperatively.

This group of patients was highly symptomatic, the most common preoperative symptoms being dyspnea and angina (Table I). Eleven patients (31%) had angina, dyspnea, and syncope or near-syncope. The New York Heart Association functional classification was as follows: 26 class III (symptoms with ordinary sedentary activity), 7 class II (symptoms with strenuous exertion), and 3 class I (asymptomatic). The 3 asymptomatic patients were children (aged 16 months and 11 and 14 years) with severe left ventricular outflow tract obstruction (gradients of 107 to 160 mm Hg).

The mean basal* left ventricular outflow peak systolic pressure gradient was 79 mm Hg (range 6 to 160): 22 patients had basal gradients of ≥70 mm Hg and 7 had gradients ≤40 mm Hg. Four of the 7 patients with low basal left ventricular outflow gradients were stimulated to gradients of 57, 92, 96, and 130 mm Hg, respectively, after the administration of isoproterenol. The left ventricular end-diastolic pressure averaged 20 mm Hg (range 7 to 37) and was normal (≤14 mm Hg) in 7 patients. Twenty-eight patients (78%) had mitral regurgitation on left ventriculography (mild 15, moderate 11, and severe 2).

The surgical approaches for septal myectomy in the 36 survivors were as follows: transaortic in 19, transventricular in 13, and combined transaortic and transventricular in 4. Since 1968, the transaortic approach alone was used. A wide and long resection of the hypertrophied muscle from the left ventricular outflow tract was accomplished with the use of cardiopulmonary bypass. One 37-year-old man required mitral valve replacement in addition because of a large perforation of the anterior leaflet of the mitral valve from infective endocarditis.

With respect to statistical methods, 1-sided sign tests were used for comparisons of preoperative versus postoperative clinical variables. The survival curve was computed by means of the Kaplan-Meier (actuarial) method.[29] To determine whether a given variable was associated with survival (for example, whether male subjects survived significantly better than female), we performed 2-sided tests.[30] Log-rank tests were used for variables that were dichotomous (such as sex); 2-sided logit-rank tests[31] were used for variables that were continuous (such as age).

Results

Symptoms at long-term follow-up: All symptoms occurred less often postoperatively than preoperatively (Table I). The most dramatically relieved symptom was angina pectoris, which decreased in frequency from 67 to 33%. Seven of 8 patients with frank syncope preoperatively had no recurrence at long-term follow-up, although an additional 2 patients had new episodes of syncope postoperatively. The disabling triad of angina, dyspnea, and syncope or near-syncope occurred in 11 patients (31%) preoperatively and in only 2 patients (6%) postoperatively ($p < 0.011$).

Electrocardiographic abnormalities: The most common arrhythmia documented at long-term follow-up was atrial fibrillation, which occurred in 12 patients (33%); it was paroxysmal in 4 and sustained in 8. Two of these patients were the only 2 who had atrial fibrillation preoperatively. One patient with chronic atrial fibrillation is in functional class III, and 7 patients with postoperative atrial fibrillation are dead. However, atrial fibrillation was not invariably associated with clinical deterioration. Four patients with atrial fibrillation, known to be present for 2 to 13 years, are in class I or II; 1 of them has required implantation of a permanent pacemaker for slow ventricular rate. One systemic and 2 pulmonary embolic events occurred in patients with atrial fibrillation, none of whom were taking anticoagulant medication. No embolic event occurred in patients who were not in atrial fibrillation.

Complete heart block was present in 2 patients, 1 as an operative complication and the other as an acquired condition 4 years postoperatively in a setting of right bundle branch block and left axis deviation. Both of these patients are being controlled with permanent implanted ventricular demand pacemakers and are in class I and II, respectively. The most common new postoperative conduction abnormality was left bundle branch block in 15 of 36 patients (42%). Intraventricular conduction delay occurred in 7 of 36 (19%) and new right bundle branch block occurred in 4 of 36 (11%) patients. The presence of postoperative left bundle branch block was analyzed as a discrete variable and it was found not to be predictive of death versus survivorship.

The data were analyzed to determine whether electrocardiographic voltage of left ventricular hypertrophy regressed postoperatively with relief of outflow obstruction. This question remains unanswered because conduction defects were a common finding after surgery and made pre- and postoperative electrocardiographic comparisons difficult. Hence, such a comparison was feasible in only 10 patients who had evidence of left ventricular hypertrophy on the preoperative electrocardiogram. Their postoperative electrocardiogram demonstrated left ventricular hypertrophy unchanged in 4, present with decreased voltage in 2, and absent in 4. Postoperative conduction defects and axis shifts also made comparisons of pathologic Q waves difficult. These were present on electrocardiograms in 13 of 36 patients (36%) preoperatively. Pathologic Q waves disappeared after myectomy in 10 of 13 patients and new pathologic Q waves appeared postoperatively in 3 patients.

Postoperative cardiac catheterization data: Cardiac catheterization was performed in 22 patients at a mean interval of 7 years after operation. The decision to perform catheterization was made clinically on an individual basis by the patients' physician. Although these 22 patients are a select subgroup and may not

* The term *basal* refers to the resting state, not influenced by drug or exercise intervention.

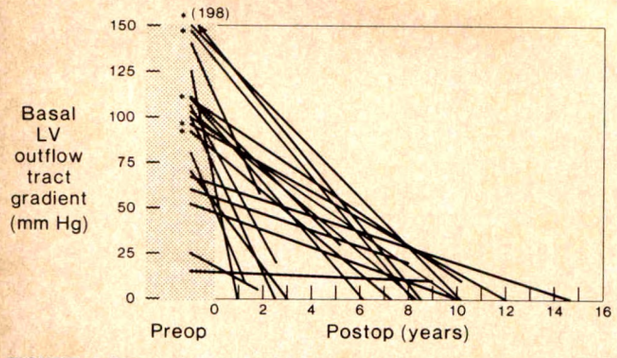

FIGURE 1. Comparison of basal left ventricular (LV) outflow gradient pre- and postoperatively. Data were obtained in 20 patients. **Asterisks** = provoked.

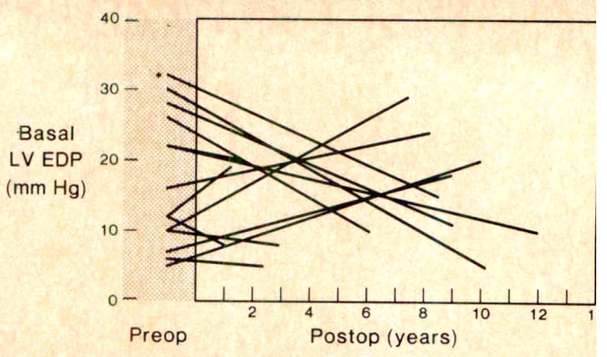

FIGURE 2. Comparison of basal left ventricular end-diastolic pressure (LV EDP) pre- and postoperatively. Data were obtained in 15 patients. **Asterisk** = provoked.

reflect the experience of all 36 patients, some trends are apparent. Figure 1 displays postoperative basal peak gradients across the left ventricular outflow tract compared with the preoperative basal values. A decrease was observed in all 22 patients. The mean postoperative gradient was 8 mm Hg compared with 79 mm Hg preoperatively ($p < 0.001$). All had postoperative gradients ≤20 mm Hg, except for 1 patient with a gradient of 58 mm Hg (preoperative gradient 140 mm Hg). Left ventricular end-diastolic pressures showed no significant change from the preoperative values (Fig. 2), decreases being observed in 8 of 14 patients. Left ventricular end-diastolic pressure was normal after myectomy in 7 of the patients who were catheterized, and all of these patients were alive in functional class I or II at follow-up.

Mitral regurgitation was found in 28 of 36 patients (78%) preoperatively and in only 6 patients postoperatively. However, because the entire study group has not had postoperative left ventriculography, the precise incidence of postoperative mitral regurgitation is unknown. In the patients who had left ventriculographic data available both pre- and postoperatively, mitral regurgitation was present in 13 before myectomy and in 5 postoperatively. In none of these comparison patients was the degree of mitral regurgitation worse after myectomy, and in no patient did it appear when there was none preoperatively.

The new finding of mild aortic regurgitation was documented at catheterization in 2 patients and on clinical examination in 2 patients. Of interest, all 4 had undergone myectomy through the aortic approach. In contrast, no aortic regurgitation was found in patients in whom the transventricular or combined approach had been used. Tricuspid regurgitation was reported in 2 patients and a small ventricular septal defect (Q_p/Q_s 1.4) in 1. Coronary angiography was performed in only 3 patients with angina preoperatively. Information on coronary anatomy was present in 7 patients at follow-up: 6 by angiography and 1 by autopsy. Of the 3 patients with preoperative angiograms, 2 had postoperative studies. One had significant progression of the disease over a period of 7 years (minor disease of the circumflex artery preoperatively to totally occluded left anterior descending artery and 70% obstruction of the right coronary artery), and the other had normal coronary arteries pre- and postoperatively. Three patients had high-grade obstructive coronary artery disease in 2 or 3 major vessels; 4 patients had minimal or no coronary artery disease. The 2 patients with 3-vessel disease and 1 with no significant disease are in the death group.

The data were analyzed in an attempt to find preoperative hemodynamic predictors for death versus postoperative survivorship. There was no statistically significant association between survival and preoperative basal left ventricular outflow gradient or left ventricular end-diastolic pressure.

Postoperative echocardiography: M-mode echocardiographic data were available in 25 patients at a mean of 10 years postoperatively. The most notable finding was a normal left ventricular cavity size (left ventricular internal dimension in diastole, ≤56 mm) and normal function in all 25. The left atrial size was normal (19 to 40 mm) in 12 and enlarged (43 to 52 mm) in 13. Mild systolic anterior motion of the mitral valve was present in 11 patients; cardiac catheterization data, which were available in 6 of these 11 patients, showed no significant residual basal gradient (0 to 20 mm Hg).

Deaths: Ten late deaths occurred (after a mean of 13.4 years of follow-up), leaving 26 long-term survivors.

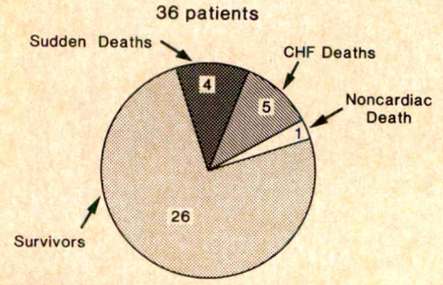

FIGURE 3. Mortality (cardiac and noncardiac) and survivorship in 36 patients surviving septal myectomy. Follow-up is 7 to 19 years (mean 11.7). CHF = congestive heart failure.

TABLE II Sudden Death Group (4 Patients)

Age at Death (yr)	Sex	Postoperative Survival (yr)	Electrocardiogram at Last Follow-Up	NYHA Class (I to IV) (Preoperative/Postoperative)	Drug Therapy Preceding Death
14	F	1.8	WPW	II/II	Digoxin
21	M	1.7	LBBB, LAD	II/II	Propranolol
27	M	10	LBBB, AF	III/I	None
47	F	3.7	LBBB, AF	III/I	None

AF = atrial fibrillation; LAD = left axis deviation; LBBB = left bundle branch block; WPW = Wolff-Parkinson-White syndrome.

TABLE III Intractable Congestive Heart Failure Group (5 Patients)

Age at Death (yr)	Sex	Postoperative Survival (yr)	Electrocardiographic Findings at Last Follow-Up	Associated Conditions	Drug Therapy Preceding Death
40	F	17.1	AF, LAD, IVCD	Pulmonary embolism	Digoxin, propranolol, quinidine, anticoagulant
47	F	10.4	RBBB, LAD, AF	Myocardial infarction	Digoxin, diuretic, procainamide, anticoagulant
48	M	11.5	LBBB, LAD, AF	ASHD	Digoxin, diuretic
55	F	8.0	LAD, anterior infarct pattern, AF	COPD	Digoxin, propranolol, diuretic, anticoagulant
57	M	8.7	LBBB, AF	ASHD, bowel infarction	Isosorbide dinitrate

AF = atrial fibrillation; LAD = left axis deviation; LBBB = left bundle branch block; WPW = Wolff-Parkinson-White syndrome.

Four deaths were sudden, 5 were from congestive heart failure, and 1 was from a noncardiac cause (metastatic breast cancer) (Fig. 3).

The deaths were analyzed from the standpoint of several discrete and continuous variables to find predictors of death versus survivorship. Of the 9 cardiac deaths, 4 occurred in the group in which myectomy was performed from the transaortic approach (4 of 19, or 21%) and 5 in those with the ventricular or combined approach (5 of 17, or 29%). This apparently higher incidence of death in patients undergoing myectomy from the transventricular or combined approach did not achieve statistical significance. Furthermore, the 2 groups are not directly comparable because of differences in duration of follow-up. These differences are due to the fact that the transventricular approach was the earlier approach to myectomy at this institution. Other variables, including age at operation, preoperative functional class, and the presence of preoperative congestive heart failure or atrial fibrillation, were analyzed. No statistically significant associations with survivorship were found.

Table II gives details of the 4 patients who experienced sudden death. Sudden death occurred an average of 4.3 years postoperatively. The 4 were asymptomatic or mildly symptomatic and were engaged in sedentary activity at the time of death. Because of the early nature of the study, only 1 of these patients was taking propranolol (120 mg/day) at the time of death.

Late deaths (Table III) from intractable congestive heart failure occurred late postoperatively, at a mean of 11 years. All of these patients were in atrial fibrillation for 6 to 108 months before death. After initial clinical improvement in 2, all had deteriorated to class IV status preterminally. Documented severe 3-vessel coronary artery disease was present in 2. One patient had autopsy evidence of left ventricular cavity dilatation in the presence of massive free wall and septal hypertrophy and severe coronary artery disease. Other serious complicating conditions included pulmonary embolism (1 patient), bowel infarction due to mesenteric artery thrombosis (1), and chronic obstructive pulmonary disease (1).

Postoperatively, the patients who died were characterized by a higher incidence of atrial fibrillation at the time of death (7 of 9, or 78%) compared with the long-term survivors at the time of follow-up (6 of 26, or 23%). Congestive heart failure and the concomitant disease were also more prevalent in the group who died.

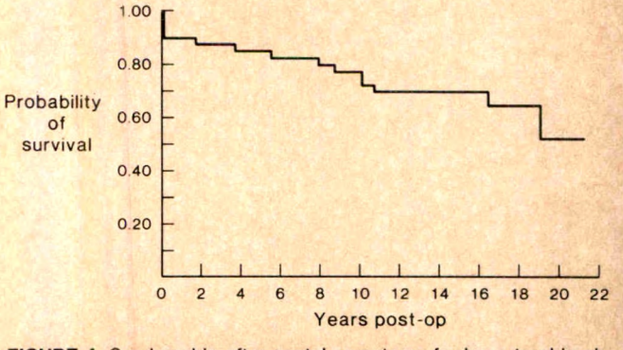

FIGURE 4. Survivorship after septal myectomy for hypertrophic obstructive cardiomyopathy, including operative mortality and postoperative deaths (excluding 1 noncardiac death).

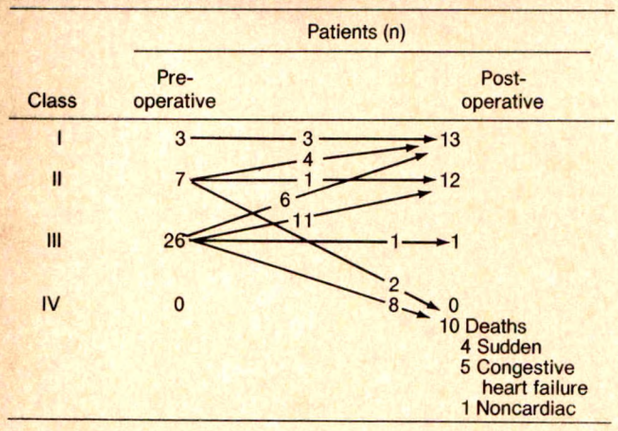
TABLE IV Functional Class in 36 Patients



Survivorship and functional status at long-term follow-up: The survival curve of the group, including 26 survivors, 4 operative deaths, and 9 cardiac deaths (excluding 1 noncardiac death), is depicted in Figure 4. The 10-year survival rate was 77.5%, including 4 operative deaths, or 86.1% when these deaths are excluded.

Also of importance is the question of whether symptomatic improvement occurs after operation and whether it is maintained over an extended follow-up period. Table IV shows the current functional status of the study group. Twenty-five survivors are either asymptomatic or mildly symptomatic. Only 1 is limited to class III status. The improvement in functional class in 3 patients was probably related to the addition of propranolol in 2 patients and the discontinuance of smoking in 1 patient whose primary symptom was dyspnea.

Overall, 21 of 26 (81%) of the long-term survivors perceived themselves as being symptomatically improved by at least 1 functional class over their preoperative status; of the remaining 5 patients, 3 continued to be asymptomatic and 2 remained in their preoperative functional class. Of note, the 3 patients who remained asymptomatic are the 3 pediatric patients with severe left ventricular outflow tract obstruction who were operated on in the hope of preventing early mortality. They have now been followed up 8.8, 13.8, and 17.0 years.

Most of the survivors are pursuing normal activities. These include the roles of active housewife (with successful pregnancies), businessman, farmer, plumber, physician, lawyer, policeman, student, and active retired person. The 2 oldest survivors are 76 and 77 years old, have been followed up 12.6 and 15.3 years, and are both in functional class II.

Discussion

This is the longest survivorship study published and represents 100% follow-up of patients in whom hypertrophic obstructive cardiomyopathy was managed by partial septal myectomy. It provides a retrospective look at 495 patient-years of follow-up in terms of significant cardiac events. Of the long-term survivors, 92% remain symptomatically improved or asymptomatic, and the symptom most frequently relieved was angina pectoris. After a mean follow-up of 13.4 years, 72% who survived operation are alive; 16 of the 36 survivors have been followed up >15 years. The overall 10-year survivorship rate, including operative mortality, was 77% (2.6% mortality per year). The postoperative (excluding operative mortality) 10-year survivorship rate was 86% (1.6% mortality per year), which parallels the National Heart, Lung, and Blood Institute's surgical experience.[14] This compares favorably with the 4% mortality per year cited in the natural history study of propranolol-treated and untreated patients with hypertrophic obstructive cardiomyopathy.[4] However, the implication that operation may increase long-term survivorship is made with caution because surgical and nonsurgical groups have not been randomized and may not be comparable. Furthermore, in this retrospective study, the influence of postoperative medical management on survivorship cannot be assessed.

The contention has been forwarded by Oakley[32] that the long-term outcome of septal myectomy is deleterious and that the left ventricular outflow gradient is abolished because of reduction in ventricular performance from myocardial damage. Although the present retrospective study lacks objective measurement of left ventricular function in all patients postoperatively, the extended long-term survivorship and favorable clinical status of these long-term survivors militate against the likelihood of significant impairment of global left ventricular function. In the patients in whom invasive and noninvasive studies are available postoperatively, we have not observed a significant increase in left ventricular end-diastolic pressure to suggest decreased ventricular compliance or left ventricular cavity dilatation on echocardiography or ventriculography to suggest myocardial damage and failure except in 1 patient with severe concomitant coronary artery disease. Our impression of adequate left ventricular performance after septal myectomy is supported by treadmill exercise studies by Redwood et al,[33] who demonstrated increased exercise performance in 89% of their study group (25 of 28 patients). In addition, radionuclide studies by Borer et al[34] showed normal or supernormal resting ejection fractions in 90% of their postmyectomy patients (19 of 21 patients).

Sudden death remains the most challenging aspect of the disease. Not only may it be the first definitive manifestation of hypertrophic cardiomyopathy,[35] but also good clinical predictors of its occurrence are lacking. In the present operative series, sudden death occurred late postoperatively in 11%. These patients were relatively young (mean age 33 years) and were doing well clinically at the time of death. The incidence of sudden death suggests that the myopathic ventricle continues to be arrhythmogenic, an aspect of the disease that operation does not appear to eliminate. Of interest, however, the presently reported sudden death rate of 11% (in surgically treated patients over an average follow-up of 13.4 years) is lower than the 18% incidence of sudden death (in a group of 101 patients treated medi-

cally over 4.7 years of follow-up) reported by Shah et al[4] and the 40% incidence of sudden death (in a group of 20 children treated medically over an average follow-up period of 7.4 years) reported by Maron et al.[36] Clinical studies by Fiddler et al[37] and McKenna et al[5] indicate that the incidence of sudden death is higher in the pediatric age group. Although the lower incidence of sudden death in the present series (which includes 9 patients 17 years of age or younger) is encouraging, the role of myectomy in preventing sudden death in young patients with hypertrophic obstructive cardiomyopathy remains to be determined.

Late postoperative death from congestive heart failure occurred in 14% of the study group at a mean of 11.1 years postoperatively. These patients were older compared with those in the sudden death group (age 40 to 57 years, mean 49), and all were in atrial fibrillation. These patients had serious concomitant diseases (coronary atherosclerosis, pulmonary embolism, chronic obstructive pulmonary disease, and bowel infarction), which were undoubtedly related to the presence of congestive heart failure and probably related to their deaths.

The present study shows, as has previously been thought, that partial septal myectomy does not prevent sudden and late cardiac death. Furthermore, preoperative predictors of postoperative death have not been found. In the present study, none of the following indexes predicted death versus survivorship: age at operation, preoperative functional class, left ventricular outflow tract gradient, left ventricular end-diastolic pressure, presence of preoperative congestive heart failure or atrial fibrillation, surgical approach, or postoperative left bundle branch block. The reason may be that, from a statistical standpoint, the number of patients in this study group is small. However, Maron et al[14] also found that surviving patients and those who died late of hypertrophic cardiomyopathy did not differ with respect to preoperative symptoms, left ventricular outflow gradient, left ventricular end-diastolic pressure, postoperative functional class, or electrocardiographic abnormalities. In the absence of preoperative predictors of operative success, timing and selection for operation are primarly dictated by the need to relieve the patient's symptoms and disability.

The surgical mortality for septal myectomy for hypertropic obstructive cardiomyopathy has declined from 10% in the first 40 patients (1959 to 1972) to 5% in the succeeding 40 patients (1973 to 1980) who were operated on at the Mayo Clinic. This is a gratifying although not a statistically significant improvement. Because of the acceptably low operative mortality and the comparatively favorable late survival and symptomatic status, we continue to believe that partial septal myectomy is indicated in the symptomatic patient with left ventricular outflow tract obstruction who is not responsive to adequate medical treatment (beta-adrenergic blocking agents, verapamil, and antiarrhythmic drugs). Although this point is controversial, the favorable outcome thus far for our 3 asymptomatic children with left ventricular outflow gradients of more than 100 mm Hg, as compared with reported results for medical management of such patients, strengthens our belief that the asymptomatic patient with severe ventricular outflow obstruction in the basal state should receive surgical consideration, especially when the patient is young.

These recommendations are made in the belief that intraventricular obstruction is an important element of this disease and that it can be alleviated, with the expectation of improved long-term survival and relief of symptoms. However, the cardiomyopathic process remains a major factor that affects the patient's ultimate course.

Acknowledgment: We are extremely grateful to C. Peter O'Brien, PhD, for his excellent help with the statistical analysis of the data presented in this report and thank Nancy LeQuia, Jamie Means, and Kaye Witte for their help in the preparation of the manuscript.

Clinical and Morphologic Cardiac Findings After Anthracycline Chemotherapy

Analysis of 64 Patients Studied at Necropsy

JEFFREY M. ISNER, MD, VICTOR J. FERRANS, MD, PhD, STEVEN R. COHEN, MD, BRUCE G. WITKIND, MD, RENU VIRMANI, MD, JOHN S. GOTTDIENER, MD, J. ROBERT BECK, MD, and WILLIAM C. ROBERTS, MD

The relation between clinical evidence of and histologic signs of anthracycline cardiotoxicity was evaluated by reviewing the clinical and morphologic findings in 64 patients studied at necropsy, all of whom had received doxorubicin or daunorubicin chemotherapy during life. Of the 64 patients, 20 (31%) had documented clinical toxicity consisting of impaired left ventricular systolic performance; in 7 (35%) of these 20 patients, histologic signs of toxicity were absent. In the remaining 13 patients with clinical toxicity, histologic signs of toxicity ranged from mild to severe. Of the 44 (69%) patients without clinical signs of drug toxicity, 21 (48%) had no histologic sign of cardiotoxicity; in 23 (52%) of the patients without clinical toxicity, however, morphologic signs of cardiotoxicity were nevertheless present—mild in most patients, but extensive in 4. Signs of extensive histologic toxicity (19 [30%] of 64 patients) were associated with large doses (>450 mg/m^2) of the drug, mediastinal irradiation, and age >70 years. This study suggests that attempts to monitor cardiotoxicity by serial evaluation of cardiac histology in patients undergoing anthracycline chemotherapy may be seriously limited by the fact that clinical evidence of toxicity may be present without histologic signs of toxicity; likewise, histologic signs of anthracycline toxicity may be present without clinical evidence of toxicity.

The anthracycline drugs doxorubicin (Adriamycin™) and daunorubicin (Daunomycin™) are 2 of the most effective chemotherapeutic agents presently available for treatment of patients with solid tumors and leukemias.[1] Cardiac toxicity is a well-recognized complication of these agents and is frequently the dose-limiting factor in their administration.[2,3] Although endomyocardial biopsy has been used in several centers to monitor patients receiving anthracycline chemotherapy,[4] limited information is available regarding the results of necropsy examination of patients who have received these drugs.[5–7] The present study was designed to determine (1) the extent of morphologic cardiotoxicity at necropsy in patients treated with anthracycline compounds, and (2) the degree to which the results of morphologic examination of necropsy hearts correlated with clinical evidence of cardiac dysfunction.

From the Pathology and Cardiology Branches, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland. Manuscript received January 5, 1983, accepted January 6, 1983.

Methods

Review of the clinical records of all patients with malignant neoplasms who died and underwent necropsy examination at the National Cancer Institute, Bethesda, Maryland, between January 1, 1970, and June 30, 1979, revealed 93 patients who had been treated with anthracyclines. In 11 patients, the gross and/or histologic material available for review was inadequate; in 18 additional patients, interpretation of both clinical and morphologic cardiac findings was complicated by medical problems such as severe anemia, renal failure, hemosiderosis, and myxedema. These 29 patients, therefore, were eliminated from further study. The remaining 64 patients form the basis of the present study. Review of gross and histologic findings and reexamination of the hearts from these 64 patients were performed without knowledge of the clinical cardiac findings.

The hearts of all 64 patients were evaluated grossly for pericardial disease, chamber dilatation, mural thrombus, and foci of fibrosis or necrosis. Histologic sections from the left ventricular free wall, ventricular septum, and right ventricular free wall were stained with hematoxylin-eosin and phosphotungstic acid hematoxylin. Each section was examined by 3 observers, who, by consensus, assigned to it a histologic score. Two characteristics were used to score the extent of histologic cardiotoxicity: vacuolization of cardiac muscle cells (Fig. 1a)

* Preejection period/left ventricular ejection time = 0.61.

CE = cardiac enlargement; CVP = central venous pressure; DA = daunorubicin; DO = doxorubicin; DIG = digitalis; Diur = diuretic; FS = fractional shortening; Histo Tox = histologic toxicity; JVD = jugular venous distention; LVd = left ventricular end-diastolic dimension; Med Irrad = mediastinal

and myofibrillar dropout (Fig. 1b). The severity of each of these 2 histologic features was assessed for each section of the myocardium according to the following scale: 0 = none, 1 = mild, 2 = moderate, and 3 = extensive. The final score of histologic cardiotoxicity for a particular patient was arrived at by adding the highest grade for vacuolization and the highest grade for myofibrillar dropout observed on any of the various sections of myocardium from the patient. For example, a patient who received a score of 2+ for vacuolization and 1+ for myofibrillar dropout would receive a final score of 3+ for histologic cardiotoxicity.

The hospital records of all 64 patients were reviewed without knowledge of the necropsy findings. Echocardiograms performed in 26 patients also were reevaluated without knowledge of necropsy findings or of the original interpretation of the study.

Statistical significance regarding characteristics of groups with and without clinical or histologic toxicity was assessed by the chi-square test.

Results

Patients with clinical evidence of drug toxicity: Of the 64 patients, 20 (31%) had clinical evidence of cardiotoxicity (Table I). These 20 patients included 10 males and 10 females, aged 5–78 years (average 29). Their total dose of anthracycline drug ranged from 85 to 900 mg/m^2 (average 450), administered over a period of 4 to 156 weeks (average 41). Four patients also received mediastinal irradiation to a total dose of 4,000, 9,450, 12,450, and 12,600 rads, respectively. In 16 of these 20 patients, evidence of cardiotoxicity included hemodynamic documentation (12 patients) (elevated central venous pressure or elevated pulmonary capillary wedge pressure, or both) and/or echocardiographic documentation of decreased fractional shortening (11 patients); in the remaining 4 patients, the diagnosis of a drug-induced cardiomyopathy was based on a combination of physical signs of cardiac decompensation (jugular venous distention, inspiratory rales, S_3 gallop sound) and radiographic signs of pulmonary venous hypertension and cardiomegaly. All 20 patients with clinical signs of drug toxicity received digoxin and 10 also received diuretics.

In 7 of the 20 patients with clinical signs of drug toxicity, the pericardial sac contained >50 ml of fluid (average 186, range 80 to 300). Two of these 7 patients had received mediastinal irradiation, and in 1 the pericardial fluid was grossly hemorrhagic; in the remaining 6 the fluid was serosanguinous. None of the 7 patients had cardiac metastases. The average heart weight in the 17 adult patients with clinical signs of drug toxicity was 358 g (range 240 to 500) (Table I). In 18 of the 20 patients, the heart weight observed exceeded that predicted according to body weight[8] by an average of 106 g. In 11 of the 20 patients, both ventricular cavities were dilated, while in 4 other patients the left ventricle alone was dilated; in the remaining 5 patients, neither ventricular cavity was dilated. The presence or absence of cavity dilatation at necropsy was *not* a function of the interval between the onset of clinical signs of toxicity and death. In 2 patients, the dilated ventricular cavities contained mural thrombus (Fig. 2); neither patient had a history of peripheral embolic events.

Histologic signs of cardiotoxicity were observed in 13 of the 20 patients with clinical signs of drug toxicity (Tables I and II): these 13 patients included 10 of the 15 patients with and 3 of the 5 without cavity dilatation. The combined histologic scores for toxicity among these 13 patients ranged from 1 to 5 (average 2.3).

irradiation; Obs = observed; PAOP = pulmonary artery occlusion pressure; Pred = predicted; PVH = pulmonary vascular hypertension; Rx = treatment; Sx = symptoms; + = present; 0 = absent.

In contrast to the previous 13 patients, histologic signs of cardiotoxicity were absent from multiple sections of myocardium in 7 of the 20 patients with clinical signs of drug toxicity (*Table I*). These 7 patients included 5 patients with and 2 without cavity dilatation. The 7 patients in whom clinical evidence of anthracycline cardiotoxicity was *not* associated with histologic abnormalities ranged in age from 5 to 61 years. Four received up to 630 mg/m² of daunorubicin, while 3 received 210 to 500 mg/m² of doxorubicin. All had evidence on physical examination of congestive heart failure. On chest radiograms, signs of pulmonary venous hypertension were present in all, and 5 of 7 had an enlarged cardiac silhouette. Two patients had abnormal echocardiograms, 1 had abnormal systolic time intervals, and 4 had elevated venous pressures.

Patients without clinical evidence of drug toxicity: Of the 64 patients, 44 (69%) had no clinical signs of cardiotoxicity. These patients (23 males, 21 females) ranged in age from 2 to 70 years (average 44).

Three of these 44 patients had >50 ml of fluid in the pericardial sac (500, 400, and 100), while in 3 others the pericardial space was obilterated by dense, fibrous adhesions. One of the former 3 patients and all of the latter 3 had received >4,900 rads of mediastinal irradiation. The average heart weight, excluding 2 children, was 278 g (range 105 to 450). In 29 patients, the observed heart weight exceeded the predicted heart weight by an average of 65 g. Biventricular dilatation was observed in 4 patients, and mild left ventricular enlargement in 2. Left ventricular mural thrombus was found in 1 patient with no history of peripheral embolic events.

Histologic signs of cardiotoxicity were observed in 23 (52%) of the 44 patients, despite the fact that none of these 44 patients had clinical evidence of anthracycline cardiotoxicity (Table II). In 15 of the 23 patients, the histologic findings were limited to a mild degree (combined score 1/6) of vacuolization (14 patients) or myofibrillar dropout (1 patient). In the remaining 8 patients, however, more extensive morphologic changes were noted: 4 patients received combined scores of 2/6 for histologic cardiotoxicity.

TABLE II Relation of Clinical Toxicity to Type and Extent of Morphologic Toxicity

Clinical Toxicity	Patients (n)	Type and Extent of Morphologic Toxicity: Myocardial Vacuoles 0	1	2	3	Myofibrillar Loss 0	1	2	3

Totals									
n	64	31	21	9	3	47	11	6	0
%	. . .	48	33	14	5	74	17	9	0

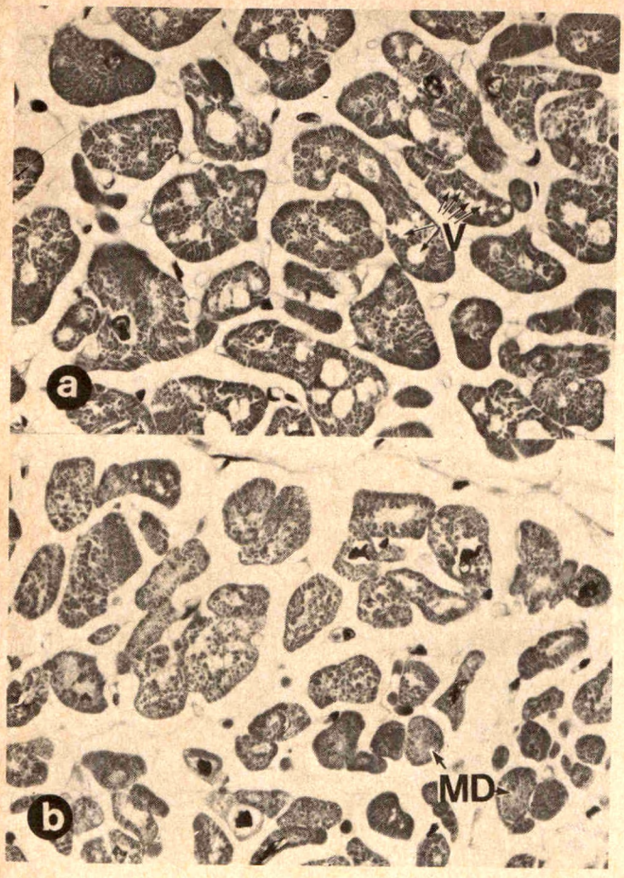

FIGURE 1. Findings used to score the extent of histologic cardiotoxicity: (**a**) vacuolization (V) of cardiac muscle cells, and (**b**) myofibrillar dropout (MD). This patient (15-year-old girl, Table I) received a histologic toxicity score of 3 (2+ vacuolization, 1+ myofibrillar dropout). (Hematoxylin and eosin stain; magnification ×500, reduced 33%.)

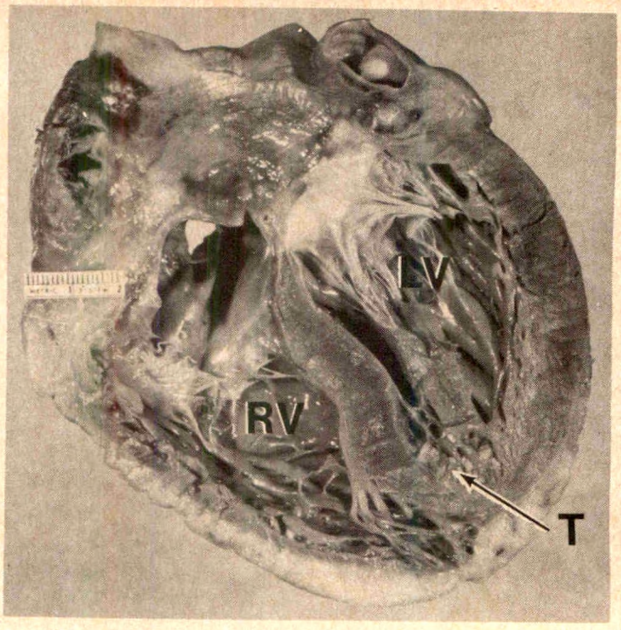

FIGURE 2. Biventricular cavity dilatation in 15-year-old girl (Table I) with clinical and histologic evidence of anthracycline cardiotoxicity. The apical portion of the dilated left ventricle (LV) contains antemortem thrombus (T). RV = right ventricle.

Patients grouped according to final (combined) scores for histologic cardiotoxicity (Fig. 3): The entire study group of 64 patients was analyzed from the standpoint of the combined score for histologic toxicity. Twenty-eight patients had a combined score of 0; 7 had clinical signs of toxicity while 21 did not. Seventeen patients received a histologic score of 1; clinical toxicity was present in 2 patients and absent in 15. Eight patients received a histologic score of 2; clinical toxicity was present in 4 and absent in 4. Seven patients received a histologic score of 3; 4 had clinical toxicity and 3 did not. Three patients received a histologic score of 4; 2 had clinical toxicity and 1 did not. Only 1 patient had a histologic score of 5 and this patient had overt clinical cardiotoxicity.

Relation between clinical cardiotoxicity and gross and histologic signs of toxicity (Fig. 4): Of the total 64 patients, 18 had neither clinical or structural evidence of cardiotoxicity. In 36 patients, histologic signs of toxicity were observed. Of these, 23 had no clinical evidence of toxicity, including 4 with dilated ventricles. Three patients had both clinical and histologic signs of toxicity unassociated with ventricular cavity dilatation. A complete "triad" of clinical, gross anatomic, and histologic signs of cardiotoxicity was observed in only 10 patients.

Of the remaining 10 patients of the study group of 64, 3 had ventricular cavity dilatation without histologic or clinical evidence of cardiotoxicity, 5 had clinical toxicity and cavity dilatation without histologic evidence of toxicity, and 2 had clinical signs of toxicity unassociated with either gross or histologic signs of toxicity. Thus, in 8 patients, cavity dilatation was not associated with histologic abnormalities.

Finally, in the entire study group of 64 patients, 20 had clinical signs of toxicity, and 2 of these patients showed no evidence of either cavity dilatation or histologic abnormalities. In 1, clinical evidence of toxicity consisted of jugular venous distention, inspiratory rales, and an S_3 gallop sound on physical examination; cardiomegaly and pulmonary venous hypertension on chest radiogram; and a central venous pressure of 20 mm Hg. The second patient also had an S_3 gallop sound, and cardiomegaly and pulmonary venous hypertension on chest radiogram. Both patients received treatment with digoxin and diuretics and 1 improved. Neither patient had pericardial fluid at necropsy.

The sensitivity of the histologic necropsy examination was calculated as follows: Patients with clinical and histologic toxicity/(patients with cardiotoxicity and histologic toxicity) + (patients with clinical toxicity without histologic toxicity) = 13/(13 + 7) = 0.65. The specificity of histologic necropsy examination was calculated as follows: Patients without clinical toxicity and without histologic toxicity/(patients without clinical toxicity and without histologic toxicity) + (patients with histologic toxicity without clinical toxicity) = 21/(21 + 23) = 0.48. The predictive value of the finding of his-

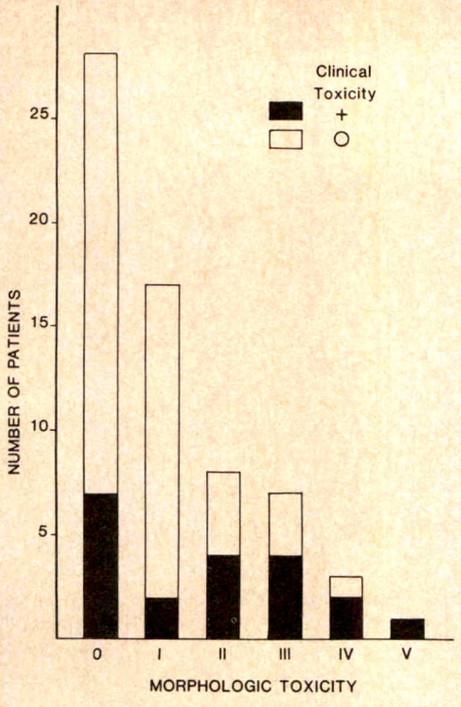

FIGURE 3. Number of patients with and without clinical evidence of cardiac toxicity in each category of histologic toxicity (see text for histologic toxicity grading system).

tologic toxicity was calculated as follows: Patients with clinical and histologic toxicity/(patients with clinical and histologic toxicity) + (patients with histologic toxicity without clinical toxicity) = 13/(13 + 23) = 0.36. This predictive value when tested proved not significantly different from random variation in toxicity (chi-square = 0.91, p >0.30).

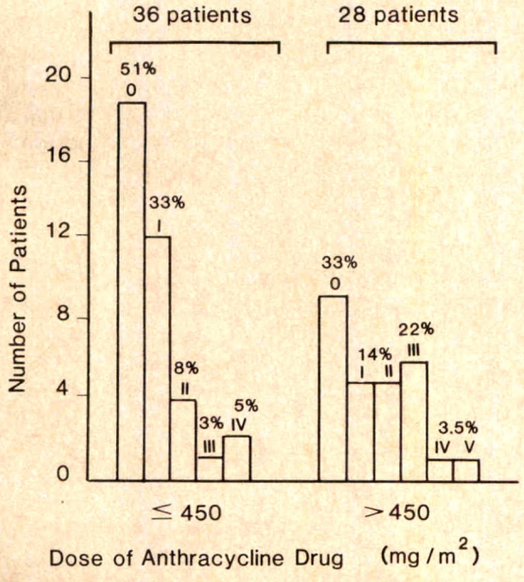

FIGURE 5. Scores for histologic toxicity grouped according to cumulative dose of anthracycline drug administered (≤450 or >450 mg/m²).

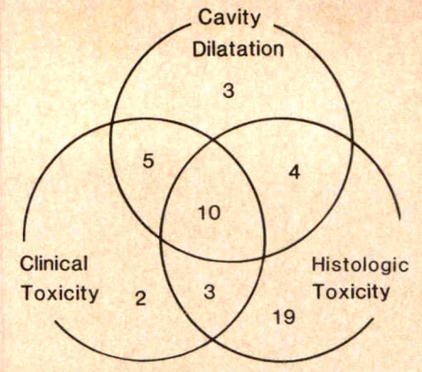

FIGURE 4. Relation of clinical cardiotoxicity to gross and histologic signs of cardiotoxicity. (Of the total 64 patients, 18 had neither clinical toxicity, cavity dilatation, nor morphologic toxicity and are not represented in this figure.)

Histologic toxicity as a function of cumulative dose of anthracycline drug: The relation between the extent of histologic signs of cardiotoxicity and the cumulative dose in mg/m² of anthracycline is illustrated in Figure 5. Of the 28 patients who received anthracycline therapy >450 mg/m², 13 (46%) had histologic scores of 2 to 5; in contrast, of 36 patients who received anthracycline therapy <450 mg/m², only 6 (17%) had histologic scores of ≥2 (p = 0.0097). Nevertheless, extensive histologic abnormalities were not limited to patients treated with >450 mg/m² of drugs: One patient treated with 100 mg/m² received a histologic toxicity score of 4 and had clinical signs of toxicity; 3 patients

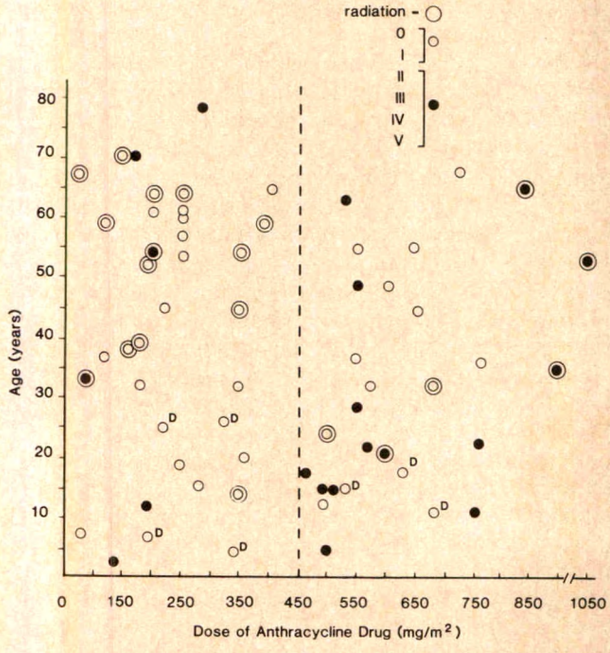

FIGURE 6. Morphologic toxicity as a function of cumulative dose of anthracycline drug, mediastinal irradiation, and age. All but 2 of the patients with scores of II to V received >450 mg/m², mediastinal irradiation, or were ≥70 years of age.

TABLE III Distribution of Histologic Changes (Morphologic Toxicity) in the Ventricular Walls of the Heart in 64 Necropsy Patients

Portion of Heart	Sections Examined (n)	Final Grade of Morphologic Toxicity						Nonrepresentative Sections
		0	I	II	III	IV	V	
Left ventricular free wall	62	26	14	8	7	3	1	3
Ventricular septum	36	12	7	6	5	0	1	5
Right ventricular free wall	50	22	7	3	5	3	1	9
Totals								
n	148	60	28	17	17	6	3	17
%	...	41	19	11	11	4	1	12

treated with 100 to 200 mg/m^2 received histologic toxicity scores of 2, 3, and 4, respectively, and 1 had clinical signs of toxicity; 2 patients treated with 200 to 300 mg/m^2 received a histologic toxicity score of 2.

Histologic toxicity as a function of cumulative drug, dose, age, and mediastinal irradiation: The effects of increasing age and mediastinal irradiation, in combination with cumulative drug dose, are illustrated in Figure 6. Of the 19 patients with combined histologic scores of 2 through 5, 13 received anthracycline therapy >450 mg/m^2. Of the 6 patients with extensive histologic changes who received <450 mg/m^2 of drug, 2 were treated with mediastinal irradiation (5,800 and 9,450 rads, respectively), and 2 were ≥70 years of age. Thus, all but 2 patients, in whom extensive histologic signs of anthracycline cardiotoxicity were recognized at necropsy, received >450 mg/m^2 of anthracycline therapy, or received combined mediastinal irradiation, or were ≥70 years of age.

Distribution of histologic abnormalities: The distribution of the histologic changes representing anthracycline cardiotoxicity is shown in Table III. Of 62 sections of left ventricular free wall from 64 patients, only 3 sections (5%) demonstrated histologic toxicity of lesser severity than was recognized in sections from either the ventricular septum or right ventricular free wall. Of 36 sections of ventricular septum taken from the 64 patients, only 5 (14%) were not representative of histologic lesions observed in sections taken from other sites of the myocardium. Of 50 sections taken from the right ventricular free wall, 9 (18%) were nonrepresentative. In those cases in which histologic toxicity was most extensive (histologic toxicity scores of 3, 4, and 5), these lesions were seen on sections taken from all 3 sites, that is, the right and left ventricular free walls and ventricular septum. The lesions corresponding to a histotoxicity score of 1 or 2 were more variable in distribution: In patients receiving a score of 1 or 2, the histologic abnormality was present in the left ventricle in 82 and 100%, respectively; in the ventricular septum in 64 and 64%; and in the right ventricular free wall in 54 and 50%.

Electrocardiographic findings in patients with and without clinical signs of drug toxicity: Electrocardiograms recorded between the time of onset of symptoms and the time of death were available in 9 of the 20 patients with clinical evidence of anthracycline toxicity. Two of the 9 patients had diminished amplitude of the QRS complex ("low voltage": ΣQRS amplitude [leads I, II, and III] ≤15 mm); in 1 of these 2 patients plus 1 other of the 9 patients, serial recordings demonstrated >30% diminution of the summated amplitude of the QRS complex in the limb leads. Pericardial heart disease was responsible for low voltage in only 1 of these patients. The mean cardiac weight of the 3 patients with reduced electrocardiographic QRS voltage was 248 g; the mean cardiac weight of the remaining 6 patients was 345 g.

Of the total group of 40 patients without clinical evidence of drug toxicity, 35 had electrocardiograms that were available for review: 11 (13%) had low voltage, including 1 with >30% diminution of the summated limb lead QRS amplitude on serial recordings. Their mean heart weight was 286 g, and none had pericardial heart disease, myxedema, cardiac amyloidosis, or hemochromatosis.

As a group, the 14 patients with low voltage and/or serial diminution in summated QRS amplitude did not differ significantly from the 30 patients with normal amplitude QRS complexes in terms of histologic findings: Vacuolar lesions were seen in 30% of the patients with and in 58% of the patients without low voltage; myofibrillar dropout in 20% of those with and in 28% of those without low voltage; interstitial fibrosis in 15% of those with and in 17% of those without low voltage; and attenuated myocytes ("fiber thinning") in 45% of the patients with versus 47% of those without low voltage.

Discussion

Anthracycline-induced cardiomyopathy was first reported by Tan et al[9] in 1967 in a 16-year-old girl treated with daunorubicin. Subsequent reports[10–14] confirmed the potential cardiotoxicity of daunorubicin and its derivative compound, doxorubicin. In the first detailed account of the morphologic findings of anthracycline-induced cardiomyopathy, Lefrak et al[5] described 2 patients in whom necropsy examination disclosed gross anatomic findings of biventricular dilatation with cavitary thrombus and histologic findings consisting of cytoplasmic hyaline transformation and cytoplasmic vacuolization. In both patients, clinical signs of a dilated cardiomyopathy had developed after they had received 720 and 825 mg/m^2 of doxorubicin.

Cortes et al[7] subsequently studied at necropsy 51 patients with doxorubicin, 17 (33%) of whom had signs of "toxic cardiopathy," defined as a combination of "intracellular edema, intracellular vacuolization, and myocardial fibrosis"; 5 had had congestive heart failure before death, and the remaining 12 never had overt cardiac failure.

Subsequent to these early necropsy observations, most published information regarding morphologic findings in patients receiving anthracycline drugs has been derived from analysis of myocardial biopsy specimens obtained from patients undergoing anthracycline chemotherapy.[4] Interest in this technique developed principally from 2 observations: (1) Although the development of anthracycline cardiotoxicity in general correlated with cumulative drug dose, in certain patients serious cardiotoxicity developed at relatively low doses,[15–19] while others, clearly in need of continuing chemotherapy, tolerated higher doses of the drug without adverse effects.[20] (2) Noninvasive methods contemporary to the early 1970s (electrocardiography, systolic-time intervals, echocardiography) proved unreliable for detecting latent, subclinical cardiac toxicity.[21–26] Thus, it was hoped that evaluation of serial biopsies might detect signs of potential cardiotoxicity before the time when cardiotoxicity became inevitable, and furthermore that biopsy analysis might predict how much longer a given patient could safely tolerate continued administration of anthracycline therapy.

The present study was designed to evaluate the correlation between clinical and morphologic signs of anthracycline cardiac toxicity in patients studied at necropsy. Examination of necropsy specimens eliminates the potential pitfalls posed by biopsy specimens, particularly the small size of tissue specimen,[27,28] limitation of sampling to subendomyocardial myocardium, and access to only 1 cardiac ventricle.[29] In addition, we hoped to extend the experience of Cortes et al[7] by (1) evaluating the pathologic material without knowledge of the clinical history, and (2) by establishing more rigid criteria for the definition of clinical and histologic signs of cardiotoxicity.

The present investigation suggests that prediction of clinical anthracycline cardiotoxicity on the basis of histologic changes is uncertain, because correlation between morphologic and functional changes is imperfect. Histologic signs of anthracycline cardiotoxicity may be absent, despite unequivocal clinical signs of a dilated cardiomyopathy: this situation was observed in 7 (35%) of our 20 patients. This finding has 3 important implications. The first, regarding therapy, is that in these 7 patients, an endomyocardial biopsy performed before the development of overt congestive heart failure would have suggested that treatment with anthracycline drugs could be continued safely. The second is that at least some of the "false-negative" results described in patients studied by the biopsy technique[22] are unlikely to have resulted simply from sampling errors. The third is that myofibrillar dropout and dilatation of the sarcoplasmic reticulum are not the only factors involved in the pathogenesis of anthracycline-induced cardiac failure. The concept that such failure is simply the result of structural damage to tissue represents an oversimplification of a very complex series of morphologic and biochemical changes.

The counterpart of the foregoing findings is that histologic signs of cardiotoxicity may be present without clinical signs of cardiac dysfunction: this situation was observed in 23 (52%) of 44 patients in the present report. Histologic signs of toxicity unassociated with clinical toxicity have been observed frequently in patients studied by endomyocardial biopsy, and, if extensive, have been interpreted as a contraindication to continued administration of anthracycline chemotherapy in these patients. The finding of morphologic toxicity in an asymptomatic patient—in the biopsy and, now, necropsy experience—suggests that such subclinical morphologic alteration may be the basis for the development of latent cardiac dysfunction described in long-term survivors of anthracycline therapy.[30,31] In nonhuman animal models of anthracycline toxicity, delayed development of cardiomyopathy has been observed as long as 6 months after discontinuation of therapy, and has been interpreted as evidence that the myocardial effects of anthracycline compounds are cumulative and irreversible.[32]

The serious discrepancies between morphologic and clinical evidence of toxicity found in the present investigation suggests that morphologic monitoring of patients receiving anthracycline drugs is of limited value for predicting the development of anthracycline cardiomyopathy. In contrast, physiologic evaluation of the cardiac response to exercise[26,31,33] or increased afterload[34] may improve the sensitivity of monitoring such patients for clinical evidence of latent cardiotoxicity. Long-term follow-up of such patients will determine whether such latent toxicity ultimately progresses to overt congestive heart failure.

Because this was a retrospective study and necropsy material from these patients had not been routinely preserved in glutaraldehyde fixative, examination of material was by necessity limited to gross anatomic and light microscopic studies. Nevertheless, as has been pointed out before, the morphologic lesions of anthracycline toxicity are evident by light microscopy.[27]

Electrocardiographic changes (low voltage or serial reduction $\geq$30% in limb lead voltage) previously proposed as evidence of anthracycline cardiotoxicity[35] correlated poorly with signs of morphologic toxicity in our patients, a finding noted previously by others.[23,36] The finding of low voltage was related to cardiac atrophy in patients with systemic cachexia, rather than to drug toxicity. The finding that cardiac atrophy frequently forms the morphologic basis for diminished QRS amplitude in such patients[37] makes this electrocardiographic feature particularly unsuitable for monitoring patients likely to be cachectic by virtue of their systemic illness.

Finally, our findings confirm observations made previously by Von Hoff,[2] Bristow,[33] and Billingham[38] regarding "risk factors" for anthracycline cardiotoxicity. Extensive morphologic toxicity was observed, with 2 exceptions, only in patients treated with >450 mg/m^2 of drug, or in patients in whom a smaller dose was ad-

ministered in association with mediastinal irradiation or to a patient ≥70 years of age. These findings support the concept of empiric limitation of total dose of drug, if possible, to <450 mg/m^2, and to an even smaller total in patients likely to receive mediastinal irradiation and in patients ≥70 years of age. Nevertheless, the finding of clinical or morphologic toxicity in patients treated with lower total doses of drug unassociated with mediastinal irradiation or advanced age suggests that empiric limitation of total dose of anthracycline is not by itself adequate to protect against the cardiotoxic effects of these drugs and mandates some form of associated monitoring.

A COMPREHENSIVE LIST OF NEW BOOKS FROM LEA & FEBIGER

■ **CARDIAC RHYTHM DISTURBANCES: A Step by Step Approach**
By WILLIAM FOX, M.D., *University of Chicago School of Medicine, Chicago, Illinois; and* EMANUEL STEIN, M.D., *Eastern Virginia Medical School, Norfolk, Virginia.* This is a skillfully written "how to" book on the interpretation of electrocardiograms. In addition to being an excellent teaching tool, it also serves as an atlas illustrating the vast majority of rhythm disturbances encountered in clinical practice. The ECG and section sequences are organized so as to supplement understanding. *287 pp. (8½ x 11), 241 ECGs (many with more than one tracing), 13 figures, 18 tables, 1983, $34.50.*

■ **PROGRESS IN CARDIOLOGY. 11**
Edited by PAUL N. YU, M.D., *University of Rochester School of Medicine and Dentistry, Rochester, New York; and* JOHN F. GOODWIN, M.D., *Royal Postgraduate Medical School, London, England.* Practical, informative and timely, this treatise addresses a host of interesting and authoritative reviews of some of the most important problems in cardiovascular medicine. This is the newest volume of an annual series which has served as the principle authoritative source of the most up-to-date information in cardiology. Clarity in style makes this an indispensable reference. *195 pp. (7 x 10), illus., 1982, $30.00.*

■ **RAPID INTERPRETATION OF HEART SOUNDS AND MURMURS**
By EMANUEL STEIN, M.D., *Eastern Virginia Medical School, Norfolk, Virginia.* There are and have been tapes of heart-sounds, but none so well-done, so comprehensible, so listenable as this one. From the opening lub dub to the last lingering murmur, you'll find this tape and workbook a learning experience. Throughout, the author gives the listener opportunities to test him or herself, and reinforces the hearing experience with helpful visual aids in the workbook. *56 pp. (7 x 10), 31 illus., tape and workbook, paperback, 1983, $18.50.*

■ **CORONARY ARTERY DISEASE IN INFANTS AND CHILDREN**
By HENRY N. NEUFELD, M.D. *and* ADAM SCHNEEWEISS, M.D., *both of Tel Aviv University Sackler School of Medicine, Tel-Hashomer, Israel.* Doctors Neufeld and Schneeweiss, both respected professionals in their field, have written a comprehensive treatise on all aspects of coronary artery disease in infants and children. Congenital coronary disease, non-atherosclerotic coronary disease, and risk factors of coronary atherosclerosis in infancy and childhood, are only some of the topics discussed. *189 pp. (7 x 10), 125 illus., tables, references, 1983, Ready Soon.*

■ **THE ELECTROCARDIOGRAM IN INFANTS AND CHILDREN: A Systematic Approach**
By ARTHUR GARSON, JR., M.D., *Baylor College of Medicine and Texas Children's Hospital, Houston, Texas.* A large pool of new information on the electrocardiogram in the child has expanded tremendously even within the last five years. Arthur Garson has taken this opportunity to condense much of this information and to apply his own extensive knowledge to reassess fundamental concepts of investigative electrophysiology and their application in the interpretation of the clinical electrocardiogram. *About 250 pp. (7¼ x 10¼), 316 illus., 32 tables, Summer 1983.*

■ **DOPPLER ULTRASOUND IN CARDIOLOGY: Physical Principles and Clinical Applications**
By LIV HATLE, M.D., *University of Trondheim, Department of Medicine, Trondheim, Norway; and* BJORN ANGELSEN, dr. techn., *The Foundation of Scientific and Industrial Research at the Norwegian Institute of Technology, Trondheim, Norway.* The application of ultrasonic techniques for noninvasive diagnosis of the cardiovascular system has become increasingly popular in recent years. This unique book presents new research and new means of using Doppler technique in cardiology, including physical principles. *238 pp., 175 illus., 1982, $27.00.*

■ **CROSS-SECTIONAL ECHOCARDIOGRAPHY**
By ARTHUR E. WEYMAN, M.D., *Harvard Medical School, Boston, Massachusetts.* This new book presents a comprehensive review of the historical development, physical principles, techniques and clinical applications of cross-sectional echocardiography. Although extensively illustrated, the reader is taken well beyond simple pattern recognition. A detailed and consistent method for cross-sectional image recording and interpretation is presented. Since it is primarily the work of a single author, the text is balanced, comprehensive, and free of redundancy. *526 pp. (7 x 10), 401 illus., 1982, $48.50.*

■ **FUNDAMENTAL CARDIOVASCULAR AND PULMONARY PHYSIOLOGY: An Integrated Approach for Medicine**
By JERRY FRANKLIN GREEN, Ph.D., *University of California School of Medicine, Davis.* This complete text is the only book which offers a complete and well-balanced review of both cardiovascular and pulmonary physiology under one cover. Basic concepts of volume-pressure and pressure-flow relationships as well as transport processes are discussed. A separate section is devoted to each of three topics: cardiac, vascular, and pulmonary physiology. *347 pp., 141 illus., tables, 1982, $20.00.*

GUP. HA[illegible]DS-O[illegible]

Microprobe.™

Go ahead, put your hand right over this photograph. It's actual size and it will give you a good idea of just how small our Microprobe™ really is. It's the smallest and lightest mechanical sector probe in Echocardiography. And you know the inherent imaging benefits of that. Like a phased array probe, Microprobe's™ small size provides maneuverability when performing difficult cardiology studies, not to mention operator and patient comfort. Our wide variety of probe frequencies, and our simple push-pull locking connector between the probe, coupled to a lightweight, flexible cable lets you change probes and applications in seconds. And we make them ourselves. All parts of the Microprobes™ are manufactured by EkoLine, which means we're sure of the quality and can maintain our advanced probe technology. Like the best conventional mechanical sector probes, Microprobe™ provides superior 2-D image quality. Plus it also gives you the best M-Mode in the industry. But don't take our word for it—try it on *your* difficult patients. Call Debbie Gentry toll free outside California at (800) 538-1556, inside California at (408) 732-6010 for a real hands-on demonstration.

(Actual Size)

E K O L I N E [illegible] N

In diagnostic ultrasound, Microprobe™ is a trademark belonging only to EkoLine.

DEMONSTRATION

EKO 5010.™
Our EKO 5010™ Ultrasound System proves the old adage that good things come in small packages. It combines ease of use, cost-effectiveness and portability with the best M-Mode in cardiology and superior 2-D cardiac imaging. And with the 5010, there is no compromise in image quality or electronics. That's because you get the same basic imaging capabilities found in our other systems. Like TGC control with 9 slide pots to optimize resolution and image quality throughout the entire field of view. Plus, when you add our Video Page Printer option, paper savings over the life of the instrument will pay for the system. And the Video Page Printer is one-third the cost of a strip chart recorder. And, of course, at the other end of all this is our exclusive Microprobe.™

EKO 5500D.™
Our EKO 5500D™ offers everything our 5010 does. And much more. It provides totally integrated pulsed and continuous wave doppler, for a complete diagnostic study. Plus, it's easy to operate. With the programmable footswitch, you can select the imaging modes you need—M-Mode, 2-D, doppler and strobe, allowing you to concentrate on the patient, not the system. But if your immediate needs don't call for doppler, there's the EKO 5000.™ It has all the features of the 5500 system, including automatic TGC, alphanumeric keyboard and strip chart recorder. And, you guessed it, all of our exclusive Microprobes™ simply plug right in.

NOW...FOR OPTIMAL HEMODYNAMIC RESPONSE
(nitroglycerin) TRIDIL®
THE IV NITRO
Tridil™
Tridil™
Tridil™
10 ml
© 1982 American Critical Care
Division of American Hospital Supply Corporation
Tridil is a concentrated drug which must be diluted prior to use.

IN CHF ASSOCIATED WITH ACUTE MI

SYSTEM THAT DELIVERS

Efficacy:

- Quickly relieves pulmonary congestion with little effect on cardiac output[1]
- Helps redistribute blood flow to the infarcted myocardium[2,3]

Predictability:

- Produces dose-responsive venous and arterial dilation to help control both preload and afterload
- Tridilset,™ a special non-absorbing IV administration set, delivers Tridil with the greatest possible accuracy[4,5]

Safety:

- Metabolites have only minor activity and are rapidly excreted
- Highly concentrated Tridil (5 mg/ml) helps avoid the risk of fluid overload (especially helpful in the presence of oliguria)

TRIDIL SYSTEM—the preferred IV nitroglycerin in CHF associated with acute MI

- Highest concentration currently available—easy dilution, convenient administration, conserves fluid intake.
- Non-absorbing Tridilset IV set allows precise titration
- Comprehensive clinical/technical support

TRIDIL SYSTEM

delivers a new level of therapeutic precision to the treatment of CHF associated with acute MI

lease see the following page for a brief summary of prescribing information.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION
SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS
TRIDIL should not be administered to individuals with:
1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS
1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinylchloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,™ an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS
TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility
No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy
Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers
It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use
The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS
The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE
Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION
(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION
TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED
NDC 0094-0090-10. 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

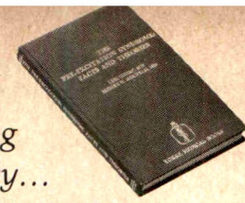
Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...



THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC
Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD

Mexiletine for Control of Drug-Resistant Ventricular Tachycardia: Clinical and Electrophysiologic Results in 44 Patients

LAWRENCE E. WASPE, MD,* HARVEY L. WAXMAN, MD, ALFRED E. BUXTON, MD,† and MARK E. JOSEPHSON, MD‡

The antiarrhythmic efficacy of mexiletine was evaluated in 44 patients with drug-resistant ventricular tachyarrhythmias. In 33 of these patients, the efficacy of mexiletine was assessed on the basis of the results of programmed ventricular stimulation. Mexiletine did not alter the ventricular effective refractory period, the Q-Tc interval, or the methods of tachyarrhythmia induction and termination during programmed stimulation. The mean cycle length of ventricular tachycardia (VT) increased from 270 ± 49 to 313 ± 80 ms in 21 patients in whom VT remained inducible on mexiletine alone ($p < 0.002$). Overall, VT remained inducible with methods similar to control (no drugs) inductions in 25 patients receiving mexiletine alone or in combination with a type I agent. VT induction was prevented in only 8 patients, 3 on mexiletine alone and 5 receiving mexiletine combined with another drug. Mexiletine alone (in 2 patients) or with another agent (in 3) suppressed clinical recurrence of VT in an additional 5 of 11 patients who did not undergo electrophysiologic study. These 13 patients were discharged on mexiletine alone (5 patients) or in combination with other drugs (8 patients), and remained arrhythmia-free over a mean follow-up period of 7.7 ± 4.1 months. Adverse effects occurred in 27 of 44 patients (61%) and were gastrointestinal in 17 and/or neurologic in 22. The drug was discontinued because of adverse effects in 6 patients (14%). Thus, mexiletine has limited efficacy when used alone, but when combined with other drugs it may be useful in up to 30% of patients with drug-resistant ventricular arrhythmias. Adverse effects are relatively common.

Mexiletine, a class I antiarrhythmic agent structurally similar to lidocaine, has been undergoing clinical investigation in Europe since 1971.[1] Currently, it is being evaluated in the United States for treatment of ventricular arrhythmias. Mexiletine has been effective in suppressing ventricular arrhythmias associated with acute and chronic ischemic heart disease,[2–7] in other types of heart disease,[1,5,8] and in patients with apparently normal hearts.[1,2,4,5] Studies indicate that mexiletine can suppress ventricular arrhythmias that have been refractory to management with conventional antiarrhythmic agents.[1,5,7,9,10] Because mexiletine has a plasma half-life of 7 to 18 hours,[7,11,12] allowing for convenient dosing intervals, the drug may be useful in the long-term management of ventricular arrhythmias.[1,4,5,7]

Most studies examining mexiletine used criteria of ventricular premature complex suppression or abolition of clinical recurrence of ventricular arrhythmia to assess its efficacy.[1–9] Few studies have primarily used serial electrophysiologic testing to evaluate the usefulness of mexiletine in treating ventricular tachyarrhythmias.[10,13] In this report we present our clinical and electrophysiologic experience with mexiletine in 44 patients with ventricular tachycardia (VT) or ventricular fibrillation (VF) resistant to treatment with conventional agents.

Methods

Study patients: The study group consisted of 44 patients, 28 men and 16 women aged 28 to 79 years (mean 56 ± 13), with a history of VT or cardiac arrest whose arrhythmias were refractory to treatment with conventional drugs or other experimental antiarrhythmic agents. Twenty-nine patients had recurrent sustained VT, 7 had cardiac arrest, VF was the first arrhythmia documented, and 8 had recurrent episodes of nonsustained VT associated with syncope or near-syncope.

All patients had 1 to >25 episodes (mean 6 ± 4.9) of clinical ventricular arrhythmia before mexiletine therapy. Twenty patients (45%) had ≥1 cardiac arrests and 6 patients had ≥1 syncopal episodes. Thirty-two patients (73%) required 1 to >25 cardioversions for termination of sustained VT or VF.

Previous antiarrhythmic therapy consisted of the following: a mean of 3.4 ± 1 (range 1 to 5) conventional agents per patient, 1 to 3 drug combinations per patient in 20 cases, and at least 1 other experimental agent in 10 patients. *Failure of previous drug therapy* was defined as a documented recurrence of the patient's clinical arrhythmia, the occurrence of an unacceptable adverse effect, or continued inducibility of the arrhythmia during electrophysiologic testing.

All patients except 2 had evidence of organic heart disease including coronary artery disease in 32, idiopathic cardiomyopathy in 4, mitral valve prolapse in 2, hypertensive cardiovascular disease in 1, aortic stenosis with aortic valve replacement in 1, left ventricular aneurysm in the absence of coronary artery disease in 1, and arrhythmogenic right ventricular dysplasia in 1.

All patients with coronary artery disease had had ≥1 myocardial infarction at least 1 month before mexiletine testing. Eighteen of the 32 patients with coronary artery disease had a left ventricular aneurysm. Three patients had previous left ventricular aneurysmectomy either for attempted control of ventricular tachycardia or for hemodynamic indications.

Left ventricular ejection fraction was determined in 22 patients by cardiac catheterization and in 18 patients by nuclear blood pool scan. The mean ejection fraction was 42 ± 18% (range 15 to 85). In 30 of 32 patients with coronary artery disease, the mean ejection fraction was 38 ± 15% (range 15 to 67).

Electrophysiologic testing: Programmed ventricular stimulation was performed, using the protocol to be described, during 1 or more phases of drug evaluation in 40 of the 44 patients. For our study, there were as many as 3 phases of evaluation: (1) a control study on no antiarrhythmic medications, (2) a study on mexiletine alone, and (3) a study on mexiletine in combination with another antiarrhythmic agent. Most patients had additional electrophysiologic tests to evaluate other antiarrhythmic agents that were tried during the course of their therapy.

Electrophysiologic testing was performed with the patient in a postabsorptive, nonsedated state after written informed consent had been obtained.[14] Three or 4 multipolar electrode catheters were inserted percutaneously into femoral or antecubital veins and positioned under fluoroscopic guidance at the high right atrium, the atrioventricular junction for His bundle recording, the coronary sinus, and the right ventricular apex. Programmed stimulation was performed using pulses of 1-ms duration at twice diastolic threshold using a custom-designed programmable stimulator and an optically isolated constant current source (Bloom Associates, Narberth, Pennsylvania).

The stimulation protocol during control and all subsequent studies consisted of the introduction of single, double, and triple extrastimuli during sinus rhythm and ventricular pacing at multiple cycle lengths (600 to 400 ms) and bursts of rapid pacing (400 to 250 ms for 5 to 30 seconds) at the right ventricular apex. If VT was not induced, this protocol was repeated with the stimulating catheter at the right ventricular outflow tract. One catheter was routinely used during follow-up testing. Ventricular tachycardia was defined as *sustained* if it persisted for ≥30 seconds or required termination in less time because of hemodynamic compromise. Ventricular tachycardia was considered *nonsustained* if its duration was between 6 beats and 30 seconds, and termination was spontaneous. A *satisfactory response* to programmed stimulation was defined as failure to induce any ventricular tachyarrhythmia with the foregoing methods, or induction of only well-tolerated nonsustained VT in the course of the complete stimulation protocol.

Mexiletine administration: Mexiletine was given orally at a daily dosage of 300 to 1,200 mg in 3 divided doses. The mean maximal dose employed was 250 ± 75 mg every 8 hours. No loading dose was given. Because plasma concentrations of mexiletine were not readily available, the patients were routinely begun on 200 mg every 8 hours and the dosage was titrated upward (or downward in 2 cases) until dose-related toxicity occurred or a maximal daily dose of 1,200 mg was reached.

Electrophysiologic testing was performed to evaluate mexiletine after patients had been maintained on a maximally tolerated dose for 3 to 7 days. When combined oral therapy was evaluated by programmed stimulation, patients were maintained on a maximally tolerated dose of the additional antiarrhythmic drug for 3 to 5 days before testing. When intravenous procainamide was added to mexiletine, repeat testing was performed on the same day. Patients maintained on digoxin or propranolol, or both, for heart failure, atrial arrhythmias, or angina remained at a constant dose throughout the period of study.

In some cases, 24-hour Holter monitor recordings were obtained off medication and again on mexiletine for correlation with the results of programmed stimulation. A *therapeutic effect* attributable to mexiletine was defined as a reduction in ventricular premature complex frequency by more than 83% in comparison with the control monitoring period.[15]

The criteria by which the efficacy of mexiletine was assessed were the following: *effective* if sustained ventricular tachycardia could not be induced by programmed stimulation, or there were no spontaneous recurrences of the patient's clinical ventricular arrhythmia during the follow-up period, or both; *partially effective* if another medication that was ineffective alone was effective in combination with mexiletine, or if the number of spontaneous recurrences of a well tolerated arrhythmia decreased; and *ineffective* if arrhythmia recurrence was not favorably altered, and the patient's clinical ventricular arrhythmia remained inducible on mexiletine or mexiletine in combination with another agent, or mexiletine had to be discontinued within a few days of therapy because of intolerable adverse effects (3 cases).

Patients discharged on mexiletine were followed up for symptomatic recurrence of arrhythmia as determined by interview of the patient during regular clinic visits and by periodic telephone questioning of the patient or his physician. In all instances, reported recurrences could be verified by electrocardiographic tracings taken in emergency rooms or recorded on ambulatory monitors.

Statistical analysis of the data was performed using the paired Student's t test and chi-square analysis with Yates correction where appropriate. Data are expressed as mean ± standard deviation unless otherwise noted.

TABLE I Effect of Mexiletine on Cycle Length of Induced Ventricular Tachycardia (VT)

	Control	Mexiletine	Mexiletine + Another Agent	p	n
VT cycle length (ms), all morphologies	270 ± 39	313 ± 80	. . .	<0.002	21
VT cycle length (ms), same morphology	278 ± 50	332 ± 81	. . .	<0.001	16
VT cycle length (ms), all morphologies	247 ± 53	. . .	373 ± 113	<0.001	23
VT cycle length (ms), same morphology	265 ± 48	. . .	387 ± 105	<0.001	13

Results

Electrophysiologic observations: *Inducibility: Control versus mexiletine studies:* Ventricular arrhythmias were inducible during a control study in 37 patients. Six patients had no control study because of frequent episodic or incessant VT, and 1 patient had no inducible ventricular tachyarrhythmia. Thirty-three patients with control studies underwent electrophysiologic testing on mexiletine (23 patients) and/or mexiletine in combination with another drug (25 patients). Patients were studied on mexiletine combined with other drugs when arrhythmias remained inducible on mexiletine (15 patients) or when other agents used alone failed to prevent arrhythmia induction (10 patients).

Among 23 patients who underwent programmed stimulation on mexiletine, the following arrhythmias were induced during control studies: sustained VT in 21 patients, and polymorphic VT (torsade de pointes) degenerating into VF in 2. On mexiletine, sustained VT remained inducible in 17 patients, and nonsustained VT was initiated in 6. The response to programmed stimulation was considered satisfactory in 3 patients whose nonsustained VT on mexiletine was well tolerated (see later).

Fifteen patients who failed electrophysiologic testing on mexiletine and 10 patients who initially failed testing on other drugs underwent programmed stimulation on combined therapy. The following agents were tested in combination with mexiletine: disopyramide (3 patients), procainamide (12), propranolol (1), quinidine (8), and amiodarone (1). During control studies sustained VT was induced in 23, polymorphic ventricular tachycardia (torsade de pointes) degenerating to VF in 1, and nonsustained VT in 1. When programmed stimulation was performed on combined therapy, 20 patients still had sustained VT, 4 had nonsustained VT, and 1 patient had no inducible arrhythmia. The response to electrophysiologic testing was considered satisfactory in the latter 5 patients (see later).

A total of 11 patients without control electrophysiologic tests who had adverse effects or spontaneous arrhythmia recurrences on mexiletine did not undergo electrophysiologic evaluation on mexiletine. Their response to mexiletine was evaluated on a clinical basis (see later).

Effect of mexiletine on cycle length, induction, and termination of VT (Table I, Fig. 1): Among 23 patients with electrophysiologic studies on no drugs and on mexiletine alone, sustained or nonsustained VT remained inducible, and the cycle lengths could be compared in 21. The mean cycle length was 270 ± 49 ms on no drugs as compared with 313 ± 80 ms on mexiletine ($p < 0.002$) (Fig. 1). In 16 of these 21 patients, a morphologically similar VT was induced during the control and mexiletine studies. The VT cycle length increased in these patients from 278 ± 50 ms to 332 ± 81 ms ($p < 0.001$).

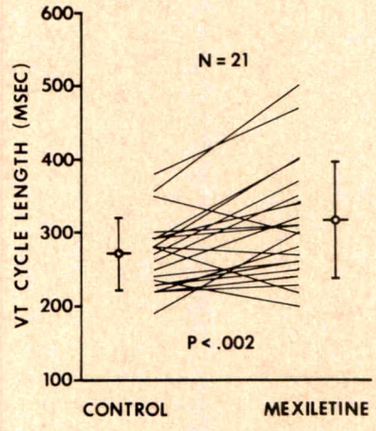

FIGURE 1. Effect of mexiletine on ventricular tachycardia (VT) cycle length. Mexiletine increased the mean cycle length of VT in 21 patients who had VT induced during control and mexiletine studies.

Among 24 patients with sustained or nonsustained VT induced on mexiletine in combination with another drug, cycle lengths could be compared with those in control studies in 23 patients. In these patients the tachycardia cycle length increased from 247 ± 53 ms during a control study to 373 ± 113 ms ($p < 0.001$). Thirteen patients had tachycardias of similar morphologies and demonstrated an increase in cycle length from 265 ± 48 ms during a control study to 387 ± 105 ms ($p < 0.001$). Patients in whom the morphologic characteristics of VT on mexiletine alone or in combination with other drugs differed from those of control studies had tachycardia configurations similar to control arrhythmias on at least 1 occasion during serial drug testing.

Among patients whose ventricular arrhythmias were inducible during control and treatment studies, mexiletine alone or in combination with other drugs did not alter the method of induction in any consistent manner. Similarly, there was no predictable change in the mode of termination.

TABLE II Mexiletine Efficacy in 44 Patients

Mex + another agent, no recurrence		3	2		

* Mexiletine partially effective because of complete suppression of incessant VT for 3.5 months before death.
† Mexiletine in combination with another drug completely suppressed incessant VT for 5 months.
‡ Complete VT suppression for 4 months.
EPS = electrophysiologic study; Mex = mexiletine; VT = sustained ventricular tachycardia.

Effect of mexiletine on refractory period and Q-Tc: Ventricular refractory periods measured during a control study and during mexiletine therapy could be compared in 13 patients. Mexiletine had no significant effect on the refractory period measured at the right ventricular apex at a paced cycle length of 600 ms: 255 ± 18 ms (control) versus 259 ± 24 ms (mexiletine) ($p = 0.33$). Refractory periods could not be compared in all patients because the site or cycle length of stimulation, or both, were not identical in both studies, or because VT was induced before refractoriness was reached.

Standardized 12-lead electrocardiograms were available for comparison on no antiarrhythmic medications and on mexiletine in 26 patients. The Q-T interval corrected by Bazett's formula was not significantly altered by mexiletine administration: 434 ± 55 ms (control) versus 426 ± 43 ms (mexiletine) ($p = 0.2$).

Efficacy of mexiletine for control of ventricular arrhythmias (Table II): The clinical efficacy of mexiletine was assessed in all 44 patients. In 3, mexiletine was stopped in 3 to 11 days because of intolerable side effects. No programmed stimulation was performed before mexiletine discontinuation, and these patients have been grouped in the ineffective category. The results in 25 patients were judged ineffective by electrophysiologic testing, and another 3 patients were classified in the ineffective group because VT spontaneously recurred soon after mexiletine was begun. Mexiletine alone (5 patients) or in combination with another drug (8 patients) provided effective or partially effective therapy in 13 patients (30%). The drug was stopped in 1 of these patients within 5 days because of adverse effects. The remaining 12 patients were followed up a mean of 7.7 ± 4.1 months (range 2.4 to 15).

Effective group: Mexiletine alone provided effective therapy in 3 (7%) of 44 patients, all of whom had sustained VT in a control study and on multiple other antiarrhythmic medications. Programmed stimulation on mexiletine alone induced only brief episodes of well-tolerated nonsustained VT in each of these patients (6 to 69 complexes). The response to testing was considered satisfactory in the patient with 69 complexes of induced VT because it was well tolerated (cycle length 400 ms). This result was clearly superior to those obtained with all other drugs. Two patients are on 900 mg/day of mexiletine, and the third is taking 600 mg/day. No patient has had a recurrence of VT over 5.5, 11.5, and 15 months of follow-up, respectively.

Partially effective group: Mexiletine was partially effective in another 10 patients (23%). Used alone, mexiletine significantly reduced the spontaneous recurrence rate of VT in 2 patients. Ventricular tachycardia, which had been incessant, was completely suppressed in both for 3.5 and 5 months, respectively. One of these patients died suddenly at the end of 3.5 months of follow-up, but is considered in the partially effective category because of mexiletine's dramatic suppressive effect before her death. Ventricular tachycardia recurred after 5 months of complete suppression in the other patient and ultimately was controlled by amiodarone plus quinidine.

Mexiletine provided partially effective therapy when combined with a previously ineffective agent in 8 cases: (procainamide, 3; disopyramide, 2; quinidine, 2; and propranolol, 1). Five of these patients, all of whom had inducible sustained VT during a control study, underwent follow-up programmed stimulation. Only well-tolerated nonsustained VT could be induced in 4. No ventricular arrhythmia was inducible in the other patient. Mexiletine was considered partially effective in these patients because combined therapy prevented the induction of sustained VT during the complete programmed stimulation protocol. All but 1 of these patients were discharged on mexiletine in combination with another antiarrhythmic agent. Eventually, mexiletine was discontinued in 2 of these patients (1 before hospital discharge) because of adverse effects. Mexiletine was stopped in a third patient because sustained VT recurred after 4 months of total suppression. The 2 remaining patients have been free of arrhythmias for 10 and 13 months, respectively.

Mexiletine in combination with another drug was partially effective in 3 other patients who did not undergo follow-up ventricular stimulation. Before therapy 1 patient had incessant VT, 1 had monthly recurrences of sustained VT, and 1 had weekly episodes of nonsustained VT associated with syncope. On mexiletine plus quinidine, the patient with incessant VT had only 1 arrhythmia recurrence after 3.5 months. After an increase in the quinidine dose, this patient has been arrhythmia-free for an additional month. Combined therapy has completely suppressed ventricular arrhythmias in the remaining 2 patients over 3.5 and 8.5 months of follow-up.

Ineffective group: Mexiletine alone or in combination with another agent was ineffective in controlling arrhythmias in 31 of 44 patients (70%). In a total of 25 patients, ventricular tachycardia remained inducible on mexiletine alone (20 of 23) patients or in combination with another antiarrhythmic drug (20 of 25) patients. Six additional patients with no follow-up electrophys-

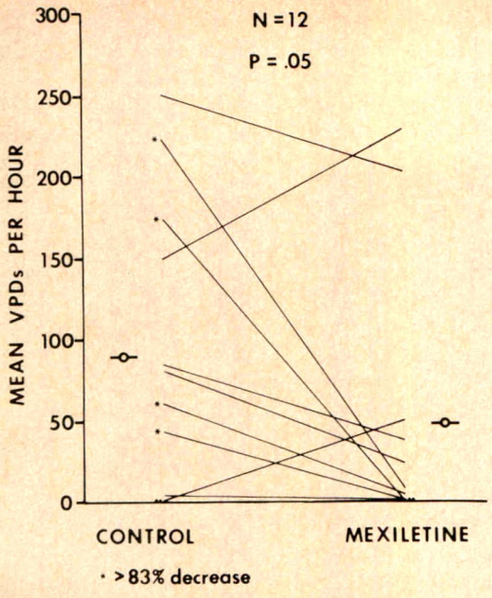

FIGURE 2. Effect of mexiletine on ventricular premature depolarization (VPD) frequency. Among 12 patients with 24-hour Holter monitors in the control state and while on mexiletine, 4 had a significant decrease in mean VPD frequency (>83%)[15] on mexiletine. Overall, the effect of mexiletine on ventricular ectopic activity was not significant (p = 0.05).

iologic testing were in the ineffective group. Three of these patients continued to have frequent clinical recurrences of VT on mexiletine alone or in combination with another drug. Mexiletine was ineffective in 3 others because of adverse effects requiring its discontinuation within 3 to 11 days.

There were 3 deaths among patients in the ineffective category. None was sudden or occurred while the patient was taking mexiletine. With 3 exceptions, the surviving 28 patients achieved satisfactory control of their ventricular arrhythmias with surgery or other experimental drugs. Ultimately, 3 patients were incompletely but best treated with conventional agents.

Results of 24-hour Holter monitoring (Fig. 2): Twenty-four-hour Holter monitors were available in 12 patients in the control state and while on mexiletine. Mexiletine decreased the mean number of ventricular premature complexes per hour from 89 ± 90 to 47 ± 81, but this was short of statistical significance (p = 0.053). Also, episodes of nonsustained VT recorded during control periods in 2 patients recurred during maximally tolerated mexiletine therapy. In 4 patients, however, a significant reduction in premature complex frequency (>83%)[15] did occur on mexiletine. Ten patients with monitoring data, including these 4, underwent electrophysiologic testing on mexiletine. Ventricular tachycardia remained inducible in 3 of the 4 patients with satisfactory Holter monitor results as well as in all 6 with inadequate results. Therefore, mexiletine efficacy as assessed by Holter monitoring in this small number of patients was limited and did not correlate with the response to programmed stimulation.

Adverse effects (Table III): Side effects developed in 27 patients (61%) while taking mexiletine, and were

TABLE III Adverse Effects

	Instances*		Reason for Drug† Discontinuation	Mean Time to Occurrence (days)
	n	%		
Gastrointestinal	17	39	2	. . .
Nausea	17	39	2	1.7 ± 1.0
Vomiting	6	14	2	1.8 ± 1.3
Neurologic	22	50	6	. . .
Lightheadedness	11	25	3	1.6 ± 1.1
Hand tremor	11	25	3	2.5 ± 1.6
Ataxia	9	20	4	1.9 ± 1.6
Confusion	2	5	0	1, 7
Blurred vision	1	2	0	4

* Patients often had more than 1 adverse effect.
† Multiple adverse effects occurred in all 6 patients requiring discontinuation of mexiletine.

severe enough to require discontinuation of the drug in 6 (14%). The mean 8 hourly dose at which adverse effects occurred was 274 ± 86 mg (range 100 to 400). This mean was not significantly different from that of the group without adverse effects (235 ± 61 mg, p >0.1) and represented the approximate median of the recommended dose range.[1–5,7,8,10,12]

Seventeen patients (39%) had gastrointestinal complaints on mexiletine. All became nauseated, and in 6 vomiting developed. With few exceptions, symptoms occurred within 1 to 4 days of mexiletine therapy, and were relieved when the 8 hourly mexiletine dose was decreased by 100 to 200 mg. In 2 patients, continued nausea and vomiting necessitated discontinuation of the drug on the third to the sixth day of treatment.

Neurologic symptoms were observed in 22 patients (50%). In order of frequency they were: lightheadedness (11), hand tremor (11), ataxia (9), confusion (2), and blurred vision (1). These symptoms also occurred early in the course of mexiletine therapy (1 to 7 days), and usually resolved with a 100 to 200 mg decrement in the 8 hourly dose. Persistent lightheadedness, ataxia, and/or tremor despite a decrease in dose was the primary or partial cause of mexiletine discontinuation in all 6 patients in whom the drug was stopped. Four patients were taking 900 mg/day, and 2 were taking 600 mg/day. Mexiletine was stopped within 11 days in 5 of 6 patients. The patients in whom confusion or blurred vision developed improved when the dose was reduced.

In 2 patients nausea and lightheadedness developed in the chronic phase of mexiletine therapy (2 to 10 months). Each had been on a stable dose of the drug. One patient improved with a dose reduction, but the other required discontinuation of mexiletine for symptom relief.

Discussion

Antiarrhythmic efficacy (Table II): We found that mexiletine provided effective or partially effective therapy for only 13 of 44 selected patients (30%) with drug-resistant VT or VF. Because several laboratories have shown that the results of electrophysiologic testing predict the long-term efficacy of antiarrhythmic agents,[16–18] the efficacy of mexiletine was evaluated principally on the basis of arrhythmia noninducibility during programmed stimulation. Of 33 patients so

tested, only 3 had no inducible sustained tachyarrhythmia on mexiletine alone, and 5 had no inducible sustained arrhythmia on mexiletine combined with other drugs. Mexiletine was classified as ineffective in 25 patients whose ventricular arrhythmias remained inducible. Mexiletine alone (in 2 patients) or in combination with other agents (in 3) suppressed clinical arrhythmia recurrences in 5 of 11 patients who did not undergo electrophysiologic testing. Therefore, these 5 patients and the 8 noninducible patients comprised the effective and partially effective groups discharged on a mexiletine regimen.

The resulting 30% efficacy rate must be further interpreted in light of the following considerations: (1) Among 13 patients discharged on mexiletine, only 5 were treated with mexiletine alone. Eight required the addition of another drug to achieve arrhythmia suppression. (2) The completely effective category consisted of only 3 patients who had no inducible sustained tachyarrhythmia on mexiletine alone. (3) Because the mean follow-up period was relatively short (7.7 ± 4.1 months), it is possible that the efficacy rate might have been lower over a longer term. (4) The efficacy of mexiletine was additionally limited during follow-up by the late death of 1 patient, late recurrences of VT in 2 patients, and by adverse effects requiring discontinuation of the drug in 2 others.

Comparison with other studies: On the basis of clinical arrhythmia suppression and reduction of premature complex frequency, other studies have reported satisfactory results in 30 to 95% of patients treated with mexiletine.[1–5,7,8,12] Two studies similar to ours in that they involved a drug-refractory population and used equivalent mexiletine doses found that VT was suppressed in 50 and 27% of patients, respectively.[7,12]

Two groups have evaluated the efficacy of mexiletine for drug-resistant ventricular arrhythmias using serial electrophysiologic testing.[10,13] DiMarco et al[10] found that mexiletine prevented the induction of VT in 42% of 41 patients evaluated by programmed stimulation. Among the patients with no inducible arrhythmias, 94% remained arrhythmia-free over a mean follow-up period of 1 year. However, Palileo et al[13] reported that sustained VT remained inducible on mexiletine in 9 of 10 patients they tested.

The overall efficacy rate observed in our study is between the extremes of the reports that evaluated mexiletine on the basis of clinical arrhythmia suppression or electrophysiologic testing. Studies in both categories dealt with a patient population similar to ours, and used comparable mexiletine doses. The high incidence of arrhythmia induction in our patients on mexiletine therapy agrees with the observations of Palileo et al.[13] Our results may have differed from those of DiMarco et al[10] because a more vigorous stimulation protocol was used. Our protocol included triple extrastimuli at 2 right ventricular sites in about one third of patients. Also, in contrast to the study of DiMarco et al,[10] our patient population did not include those with only repetitive ventricular responses which became noninducible on mexiletine therapy. We did not evaluate a sufficient number of patients solely on the basis of clinical arrhythmia suppression to make a comparison with those studies meaningful.

Electrophysiologic and 24-hour Holter monitor observations: Our findings that mexiletine significantly increased the cycle length of inducible VT, but had no effect on the ventricular effective refractory period or corrected Q-T interval have previously been noted.[7,8,13,19] As the present study emphasized the evaluation of mexiletine by programmed stimulation, only limited Holter monitor data were available. Mexiletine significantly decreased ventricular ectopic activity in a minority of our patients (4 of 12). Furthermore, significant ventricular premature complex suppression did not correlate with efficacy as assessed by programmed stimulation in these 4 patients.

Adverse effects: We observed a high incidence of adverse effects during mexiletine therapy (61%). These occurred at doses that were not significantly different from those of the group without side effects, and were similar to previously reported therapeutic dose ranges.[1–5,7,8,10,12] The untoward effects were gastrointestinal or neurologic in nature. They usually developed within the first week of therapy, and most commonly occurred within 48 hours of starting mexiletine therapy or increasing the dose. Adverse effects resolved in the majority of patients (21 of 27) by decreasing the dose and, therefore, appeared to be dose-related. We agree with others who have noted a narrow toxic to therapeutic ratio,[4,7,12] because dose adjustments that caused or relieved symptoms were small. The incidence of adverse effects reported with the use of mexiletine has ranged from 10 to 74%.[1–5,7,8,10,12] When used orally, symptoms were restricted to gastrointestinal and neurologic systems and, as in our study, occurred within the first several days of therapy.[10]

Implications: Our observations suggest that mexiletine alone or in combination with other drugs may be useful in the treatment of, at most, 30% of patients with ventricular arrhythmias resistant to conventional agents. In most patients (33), mexiletine was evaluated by electrophysiologic testing, with the assumption that this is predictive of long-term drug efficacy.[16–18] Only 8 patients (24%) had no inducible sustained arrhythmias on a mexiletine regimen. Of these, only 3 (9%) had no inducible sustained arrhythmia on mexiletine alone. Because electrophysiologic testing was carried out after several days of a maximally tolerated dose of mexiletine, the efficacy we observed was probably the highest attainable with our stimulation protocol. A study based more on clinical arrhythmia suppression and Holter monitoring might have yielded different results. However, when the small group (11 patients) we evaluated on the basis of clinical arrhythmia suppression was compared with the group evaluated by programmed stimulation, there was no significant difference in overall efficacy (5 of 11 versus 8 of 33, chi-square with Yates = 0.910, $p > 0.30$). When the use of mexiletine alone is considered, our data indicate a limited antiarrhythmic effect. Its administration is associated with a relatively high incidence of adverse effects. Therefore,

mexiletine appears to have only moderate usefulness in the treatment of patients with recurrent drug-resistant ventricular tachyarrhythmias.

Acknowledgment: We thank Kathy Cioschi, Marie Coscia, and Bettie Kaplan for secretarial assistance and Boehringer Ingelheim for supplying the mexiletine used in this study.

Possible Contribution of Encainide Metabolites to the Long-Term Antiarrhythmic Efficacy of Encainide

ROGER A. WINKLE, MD, FLORA PETERS, RN, ROBERT E. KATES, PhD, and DONALD C. HARRISON, MD

To establish long-term efficacy and the relation between drug plasma concentration and antiarrhythmic response, 12 patients with encainide-responsive frequent complex ventricular ectopic activity underwent 1 year of therapy with encainide. Twenty-four hour ambulatory electrocardiograms were obtained at baseline and every 2 months. Drug withdrawal with concomitant plasma sampling and electrocardiographic monitoring was performed at 6 and 12 months. Average group premature ventricular contraction (PVC) suppression during the year was 97 to 99%, with nearly total suppression of pairs and salvos. The most common adverse effects were transient visual disturbances and dizziness or lightheadedness. During a dose interval (6 to 12 hours) the concentration of encainide metabolites exceeded that of encainide by several-fold. The median time of arrhythmia return after drug withdrawal was 12 to 14 hours. At the time of arrhythmia return encainide was generally no longer detectable but the average concentration of O-demethylencainide and 3 methoxy-O-demethylencainide was 72 ± 49 and 172 ± 74 ng/ml, respectively. It is concluded that encainide therapy is extremely effective for continuous long-term suppression of complex ventricular arrhythmias and its metabolites contribute significantly to its antiarrhythmic action during chronic oral therapy.

Encainide is a new antiarrhythmic drug that is extremely effective for suppression of ventricular ectopic activity[1–4] and is useful for treating some patients with recurrent life-threatening ventricular tachyarrhythmias.[5] Although encainide has a short half-life of 1.9 to 3.8 hours,[1] it is effective in most patients when given on a 6 to 8 hour dosing regimen. A wide toxic to therapeutic ratio as well as the possibility of pharmacologically active metabolites have been postulated to explain this finding.[2] Encainide is known to undergo extensive metabolism to a number of compounds, including O-demethylencainide (ODE) and 3-methoxy-O-demethylencainide (MODE). Preliminary animal data[6] suggest that these compounds have pharmacologic activity and several indirect observations suggest that they contribute to encainide's antiarrhythmic activity in man. In a previous study[2] comparing the antiarrhythmic action of single oral and intravenous doses of encainide, we found that the plasma concentration of encainide required for arrhythmia suppression was higher after intravenous than after oral administration. This study was performed using a radioimmunoassay which measures primarily encainide and not its metabolites.[7] Jackman et al[8] presented data indicating that encainide's electrophysiologic effects after multiple oral doses are different from those measured after acute intravenous dosing.[9] The observations from both of these studies are consistent with the formation of pharmacologically active metabolites in greater quantities after oral as compared with intravenous dosing. The present study was initially designed to examine the long-term efficacy and safety of encainide in patients with chronic ventricular ectopic beats and to examine simultaneously the relation between encainide plasma concentration and its antiarrhythmic effects. Development of a new high pressure liquid chromatographic assay[7,10] which measures both unchanged encainide as well as its metabolites (Fig. 1) permitted us to relate arrhythmia suppression during chronic oral therapy to the plasma concentration of both encainide and its metabolites.

Methods

Patients participating in this study were those with chronic ventricular ectopic beats suppressed by encainide during participation in short-term drug efficacy protocols.[2,3] Each

patient had undergone 1 or more 24-hour ambulatory electrocardiographic recording while receiving either no antiarrhythmic drugs or a placebo. The last 24-hour recording performed without antiarrhythmic drugs or with placebo before beginning long-term maintenance therapy with encainide was taken as the baseline recording. In some patients, slight dose adjustments were carried out during the first few weeks of chronic encainide therapy and patients were seen as outpatients after 1 to 2 weeks and 1 month of therapy. After 2 and 4 months of chronic encainide therapy, patients returned to the outpatient clinic for a clinical evaluation, 12-lead electrocardiogram, and 24-hour ambulatory electrocardiographic recordings. After approximately 6 months of therapy, each subject was admitted to the hospital for 3 days and underwent continuous telemetry monitoring on a cardiac floor. On Day 1, each patient contined to take his or her daily maintenance dose of encainide and underwent a 24-hour ambulatory electrocardiographic recording. On Day 2, each patient took the last dose of encainide and a 24-hour ambulatory electrocardiogram was obtained. Blood samples were drawn with use of a heparin lock 0.5, 1, 1.5, 2, 4, 6, 8, 12, 16, and 24 hours after the last dose and stored in a glass test tube with a screw-on cap. Blood samples were spun and plasma was frozen for subsequent analysis. On Day 3, patients remained without encainide and a third 24-hour ambulatory electrocardiographic recording was performed. If the patient's arrhythmias returned, he or she was discharged with the same dose of encainide taken previously. Patients were seen in the outpatient clinic at 8 and 10 months and underwent clinical evaluation, 12-lead electrocardiogram, and 24-hour ambulatory electrocardiographic recordings. Patients were again hospitalized for 3 days after approximately 12 months of encainide therapy, and each underwent a drug withdrawal protocol similar to that performed at 6 months. Periodic laboratory safety data and ophthalmologic examinations were obtained in all patients.

Data analysis: Plasma from the 24-hour washout at 6 and 12 months was analyzed for drug concentration using a high pressure liquid chromatographic assay[7,10] which can measure unchanged encainide, ODE, MODE, and N-demethylencainide (NDE). Graphical plots of the log of the plasma concentration of encainide and each of its metabolites over time were made for each patient. Mean steady state plasma concentrations over a dose interval were calculated from the initial 6 to 8 hours of data after the final dose and a half-life was calculated from the least squares fit of the log-linear terminal portion of the log plasma concentration versus time curves.

Ambulatory electrocardiographic recordings were analyzed using the Stanford computer analysis system.[11] This provides accurate counts of total number of PVCs in each minute which were tabulated as PVCs per 15 minutes, hourly PVC count, and daily 24-hour totals. In addition, the total number of pairs and runs of ventricular ectopic beats were tabulated and verified by operator evaluation. Recordings of <24 hours' duration had the total PVC counts adjusted to reflect the shortened recording duration. The percent reductions in total ventricular ectopic beat counts at 2, 4, 6, 8, 10, and 12 months were compared with the initial baseline control recording.

For the 6- and 12-month drug withdrawals, graphical displays of PVC frequency over the 72-hour hospitalization were recorded. This included the initial 24 hours with maintenance encainide therapy and 48 hours after the final drug dose was administered. These graphs were inspected to assess the time of arrhythmia return. At the time corresponding to the return of arrhythmias, the plasma concentration of encainide and each of its metabolites was determined from the plots of drug and metabolite plasma concentration versus time. All data are reported as mean ± standard deviation.

Results

Patient population: Fourteen patients (12 men and 2 women) took part in the study. Their clinical characteristics are summarized in Table I. Two patients did not complete the 1-year trial. One patient (Patient 6) was withdrawn from the study after the 6-month drug withdrawal when it became apparent that his arrhythmias were actually supraventricular with aberration

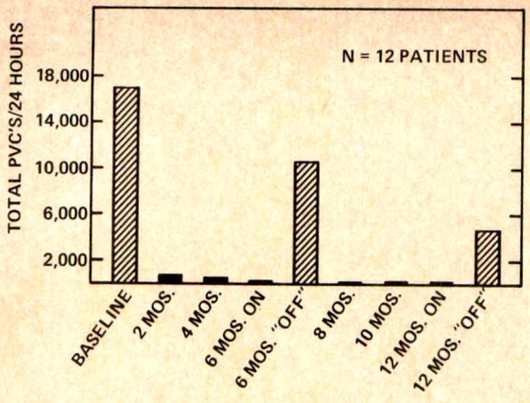

FIGURE 2. Average number of PVCs per 24 hours recorded on ambulatory electrocardiographic recordings for the 12 patients completing 1 year of encainide therapy. The crosshatched recordings done at baseline, 6 months, and 12 months were performed while the patient was not receiving ("off") encainide. However, because of the persistently high levels of encainide metabolites from 24 to 48 hours after the last dose of encainide, it is likely that the 6- and 12-month "off" encainide recordings were performed at a time when there was some persistent drug effect. This may account for the decreased number of PVCs compared with the baseline recording. The other recordings (**solid bars**) were all performed with the patient taking encainide; >95% average PVC reduction was seen on each of these recordings.

rather than ventricular in origin. The other patient (Patient 10) was withdrawn after several months of therapy because of failure to control his arrhythmias, probably due to progression of his cardiac disease (see later under Adverse Effects).

Encainide dose: The average encainide dosage was 165 ± 51 mg/day (range 100 to 250). This dosage was generally divided into 3 or 4 daily doses. Three patients underwent dosage adjustments during the 1-year period. Patient 3 had the dosage increased from 35 mg every 12 hours to 35 mg every 8 hours after approximately 4 months because she noted a return of palpitations toward the end of the dosage interval with the lower dose. Patient 4 had the dosage decreased from 50 to 37.5 mg every 6 hours because of excessive aberrant conduction of his atrial fibrillation during exercise treadmill testing. Patient 10 underwent a gradual reduction in dosage from 40 mg every 6 hours to 20 mg every 6 hours because of drug-induced sinus bradycardia with sinus pauses.

Antiarrhythmic effects: The total number of ventricular ectopic beats recorded in the baseline ambulatory electrocardiographic recordings as well as those obtained with drug therapy at 2, 4, 6, 8, 10, and 12 months are shown in Table II. The average baseline ventricular ectopic beat frequency was 17,021 ± 12,454/24 hours. Each of the ambulatory electrocardiographic recordings done with encainide revealed a marked reduction or total elimination of ventricular ectopic beats (Fig. 2). This reduction averaged well above 95% compared with the baseline value. Both the 6- and 12-month drug withdrawal recordings made from 24 and 48 hours after drug was discontinued showed a return of ventricular arrhythmias. Although the average number of ventricular ectopic beats in 24 hours was considerably higher during the drug withdrawal period than in each of the drug treatment periods, the 6-month withdrawal value of 10,469 ± 11,368 and the 12-month withdrawal value of 4,491 ± 5,340 were both below the baseline value.

Just as there was a marked reduction or total suppression of ventricular ectopic beats, there was nearly complete suppression of ventricular pairs (Table III) and ventricular salvos (Table IV). There was a distinct increase in the number of pairs and salvos at the 6- and 12-month withdrawal period, but neither returned completely to the baseline levels.

Adverse effects: Although only 2 patients were entirely free of adverse effects, in most patients the adverse effects occurred only infrequently or were of a minor nature; usually, they did not interfere with treatment. Eight patients had transient visual symptoms often described as a blurring of vision or difficulty with peripheral vision or both. Seven patients had transient lightheadedness or dizziness. Three had other central nervous system adverse effects, including intermittent tremor in 2 and a persistent facial numbness

in 1. Three patients noted a bad taste in the mouth and 2 had gastrointestinal symptoms. One patient (Patient 10) had a drug-induced exacerbation of sinus bradycardia and sinus pauses with higher encainide doses. Reduction in the encainide dose in this patient resulted in a return of ventricular arrhythmias. The patient was treated with a permanent pacemaker for his sinus pauses, but despite continuation of encainide therapy had recurrences of sustained ventricular tachycardia and progression of congestive heart failure. This patient was withdrawn from encainide and ultimately underwent cardiac transplantation. Two patients, both with a history of presyncope before encainide administration, had single isolated episodes of syncope while taking encainide. In each instance, the drug was continued in its previous dose when electrocardiographic monitoring showed no explanation for the syncopal episode.

Plasma drug concentrations: A detailed reporting of the pharmacokinetics of encainide and its metabolites in these patients is beyond the scope of this report and will be presented in detail elsewhere.[12] However, in order to understand the relation between drug levels and antiarrhythmic effect, a brief summary is necessary. All but 1 of the patients showed the same pattern of encainide and encainide metabolite plasma concentrations. Encainide levels peaked very early after the final dose and had a rapid decrease with an average half-life of 1.10 ± 0.56 hours at 6 months and 1.05 ± 0.49 hours at 12 months. Two major metabolites, ODE and MODE, were identified in the plasma of these patients. Over a dose interval at steady state, the average plasma concentration of MODE and ODE greatly exceeded those of encainide itself (Fig. 3 and 4). Over a dose interval, the ratio of the mean plasma concentration of MODE to encainide was 5.02 ± 2.61 and the ratio of ODE to encainide was 5.15 ± 4.13 at 6 months. The ratios were similar at 12 months. Each of these metabolites had a much slower decline in plasma concentration than did encainide. The average half-life* of ODE was 11.1 ± 10.2 hours at 6 months and 10.9 ± 5.7 hours at 12

* True estimation of half-life cannot be determined because the continuing formation of metabolites from encainide may have been occurring. Such a determination requires direct administration of the metabolites.

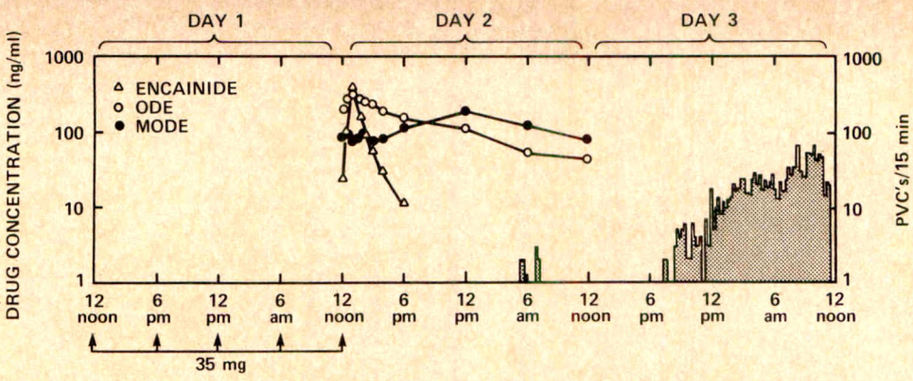

FIGURE 3. Data obtained from the 12-month withdrawal in Patient 5. Shown are the number of PVCs per 15 minutes obtained from ambulatory electrocardiographic recordings done during the 3-day withdrawal. On Day 1 the patient took 35 mg encainide every 6 hours, on Day 2 no encainide was given and blood was sampled throughout the 24-hour period, and on Day 3 the patient remained off encainide. In this patient, encainide plasma concentration (**open triangles**) peaked early and were undetectable by 6 hours after the final dose of encainide. The plasma concentration of O-demethylencainide (ODE) and 3-methoxy-O-demethylencainide (MODE) remained high throughout the 24-hour period. Although a few PVCs occurred at 6 A.M. on Day 2 (18 hours after the last dose of encainide), they do not return consistently until 32 to 38 hours after the last dose of encainide. This patient's reaction was the most striking example suggesting that antiarrhythmic effect was due to encainide's metabolites.

months. MODE was present in higher plasma concentrations and decayed even more slowly than did ODE. In fact, some patients had almost no decrease of MODE over the 24-hour washout period.

One patient (Patient 4) had a different pattern of metabolism. This patient had higher levels of and a longer half-life for encainide (3.3 hours at 6 months and 2.5 hours at 12 months) than other patients and had levels of ODE which exceeded those of MODE. Furthermore, a third metabolite, NDE, was also detected in low plasma concentrations in this patient.

Return of arrhythmias after drug withdrawal: relation to drug plasma concentration: There were a total of 24 drug withdrawals in the 12 patients completing 1 year of treatment with encainide. Eleven of these withdrawals were not suitable for evaluating the relation between arrhythmia return and encainide and encainide metabolite plasma concentration. In 2 instances the 6-month withdrawal plasma samples were not analyzed using the high pressure liquid chromatographic assay. After 4 drug withdrawals, there was no return of ventricular arrhythmias during the 48-hour washout period. In several of these instances, patients were discharged not receiving encainide, and ambulatory electrocardiographic recordings done after discharge documented a return of ventricular arrhythmias. In 5 drug withdrawals, ventricular arrhythmias definitely returned but they did so gradually and it was difficult to determine a specific time at which the arrhythmias returned. Excluding these 11 withdrawals left 13 drug withdrawal periods in which the time of return of ventricular arrhythmias was well-defined and the plasma concentrations of encainide and its metabolites were available.

After encainide withdrawal, the time of arrhythmia return ranged from approximately 6 to approximately 38 hours (median 12 to 14). In 9 of the 13 withdrawals, ventricular arrhythmias returned from 2.5 to 28 (median 8) hours *after* encainide was no longer detectable in the plasma (Fig. 3 and 4). In 2 instances ventricular ar-

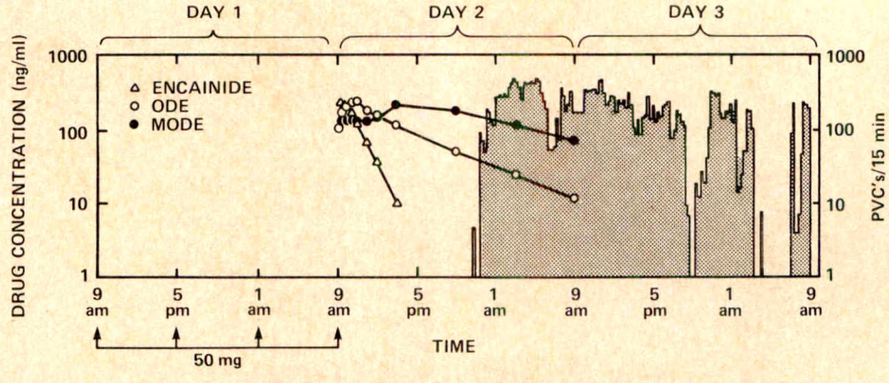

FIGURE 4. Data obtained from encainide withdrawal at 12 months in Patient 7. Premature ventricular contractions did not return until 14¼ hours after the last dose of encainide. At the time of PVC return, the ODE plasma concentration was 42 ng/ml and the MODE plasma concentration was 180 ng/ml. The last detectable encainide level occurred 6 hours after the last dose of encainide was taken, a full 8 hours before the return of PVCs.

rhythmias returned at 6 and 11 hours, which was approximately the same time as encainide decayed to undetectable levels. In only 2 drug withdrawals were there measurable encainide levels persisting beyond the time of ventricular arrhythmia return. These 2 withdrawals were both in Patient 4 who also had the unusual pattern of encainide metabolism. Excluding this patient, the average plasma concentrations of ODE and MODE at the time of ventricular arrhythmia return were 71.7 ± 49 ng/ml (range 15 to 140) and 172 ± 74 ng/ml (range 78 to 320).

Discussion

Patients entering this study were known to have had ventricular arrhythmias suppressed by short courses of oral encainide therapy. Several previous publications have indicated the drug causes nearly total ventricular ectopic beat suppression during short-term administration.[1–4] Our study documents ongoing antiarrhythmic effect over a 1-year period in a group of subjects with complex ventricular ectopic beats. The initial short-term excellent antiarrhythmic response was maintained in these subjects and ventricular ectopic beat suppression averaged well over 95% throughout the year of treatment. Perhaps more importantly the suppression of pairs and salvos was also nearly complete. These observations suggest that encainide might be an excellent antiarrhythmic agent to use in clinical trials designed to test the hypothesis that ventricular ectopic beat suppression can prevent sudden cardiac death in high-risk subgroups.

Although most subjects in this study experienced adverse effects, they were generally minor and well-tolerated. Dizziness or lightheadedness and visual disturbances were the most common adverse effects. One patient experienced dose-related worsening of bradyarrhythmias and long sinus pauses. Although in our overall experience with encainide this has been an uncommon adverse effect, it does indicate the drug has the potential to cause de novo or aggravate preexisting sinus nodal dysfunction. The same patient with the sinus pauses also had several recurrences of sustained ventricular tachycardia. While we cannot entirely exclude the possibility of encainide exacerbation of ventricular irritability,[13] overall, it seems most probable that these episodes represented a failure of the drug to control ventricular tachycardia in a patient with a progressive cardiomyopathy.

The most important finding of this study was the observation that 1 or both of the encainide metabolites, MODE and ODE, may have been contributing to the drug's antiarrhythmic activity during long-term oral therapy. During long-term oral dosing these metabolites are present in plasma concentrations which greatly exceed those of encainide itself. Because of their high plasma concentrations relative to encainide's and their considerably longer half-lives during drug withdrawal, antiarrhythmic activity persisted well beyond the time when encainide plasma concentrations become unmeasurable. Arrhythmias returned at a time when considerable plasma levels of both metabolites were present in all patients. While this evidence strongly suggests that these metabolites account for a portion of encainide's antiarrhythmic activity, the evidence is only circumstantial. We cannot determine whether this pharmacologic activity results from 1 or both of these metabolites. Nor can we entirely exclude either the possibility that encainide in extremely low and unmeasurable (using the high pressure liquid chromatographic technique) plasma concentrations or the persistence of high encainide tissue concentrations are accounting for the antiarrhythmic activity seen. Further unraveling of these points will require direct administration of MODE and ODE to patients with arrhythmias.

The finding that metabolites may account for a portion of encainide's antiarrhythmic activity has several implications for therapy with this drug. It is clear that measurement of encainide plasma concentrations alone may bear little relation to drug effect. In order for measurement of plasma drug levels to be of value, it will be necessary to learn a great deal more about the relative potency of the various metabolites and the contribution of each to antiarrhythmic action as well as adverse effects. The extremely slow decay of plasma concentration of MODE and ODE and the finding that these compounds have antiarrhythmic activity explain the fact that pharmacologic effect for encainide may persist well beyond the time when encainide itself is no longer detectable in the plasma. Furthermore, the different pattern of encainide levels and metabolite formation in 1 of our patients suggests intersubject variation may further complicate the situation. Roden et al[1] also noted intersubject variation in pattern of metabolism of encainide since 1 of 11 patients in their series did not form ODE.

Previous studies indicated that encainide had a short half-life averaging approximately 2 to 3 hours. Thus, the present study was designed with a 24-hour washout during which bloods would be obtained for drug plasma concentration. It was anticipated that encainide would be gone from the plasma by the end of 24 hours in virtually all patients; thus, the ambulatory electrocardiographic recording obtained 24 to 48 hours after the last dose of encainide would be adequate for use as a drug withdrawal ambulatory electrocardiographic recording to document the return of arrhythmias. This policy followed the usual rule of having discontinued the drug for at least 5 half-lives before making a "drug-free" recording. Although many patients had a return of arrhythmias by 24 hours after the last dose of encainide, a number of patients did not. The high level of encainide metabolites present suggests that the failure of arrhythmias to return during this time may have been due to the metabolites' presence. This may be the explanation for the fact that the 6- and 12-month withdrawals did not show a complete return of arrhythmias to baseline levels.

The presence of pharmacologically active metabolites with slow plasma decay suggests that these metabolites do not reach steady-state for several days or longer after initiation of oral maintenance encainide doses. Since these metabolites may potentially account for some of encainide's toxicity as well as its efficacy, it seems im-

portant to allow several days or more to elapse with any given maintenance dose before going to a higher dose. Further observations with regard to the accumulation of these metabolites will be necessary in order to determine when they reach steady-state plasma concentration.

Beat-to-Beat Left Ventricular Performance in Atrial Fibrillation: Radionuclide Assessment With The Computerized Nuclear Probe

JAMES SCHNEIDER, MD, HARVEY J. BERGER, MD, MILTON J. SANDS, MD, ANTHONY B. LACHMAN, MD, and BARRY L. ZARET, MD

There is wide beat-to-beat variability in cycle length and left ventricular performance in patients with atrial fibrillation. In this study, left ventricular ejection fraction and relative left ventricular volumes were evaluated on a beat-to-beat basis with the computerized nuclear probe, an instrument with sufficiently high sensitivity to allow continuous evaluation of the radionuclide time-activity curve. Of 18 patients with atrial fibrillation, 5 had mitral stenosis, 6 had mitral regurgitation, and 7 had coronary artery disease. Fifty consecutive beats were analyzed in each patient. The mean left ventricular ejection fraction ranged from 17 to 51%. There was substantial beat-to-beat variation in cycle length and left ventricular ejection fraction in all patients, including those with marked left ventricular dysfunction. In 14 patients who also underwent multiple gated cardiac blood pool imaging, there was an excellent correlation between mean ejection fraction derived from the nuclear probe and gated ejection fraction obtained by gamma camera imaging ($r = 0.90$). Based on beat-to-beat analysis, left ventricular function was dependent on relative end-diastolic volume and multiple preceding cycle lengths, but not preceding end-systolic volumes. This study demonstrates that a single value for left ventricular ejection fraction does not adequately characterize left ventricular function in patients with atrial fibrillation. Furthermore, both the mean beat-to-beat and the gated ejection fraction may underestimate left ventricular performance at rest in such patients.

Atrial fibrillation is characterized by an irregularly irregular ventricular response resulting in marked variations in beat-to-beat left ventricular function. Although several studies have evaluated the determinants of beat-to-beat left ventricular performance in this arrhythmia, these studies have been limited partially by methodologic constraints.[1–8] They generally have not allowed direct assessment of left ventricular function in a sufficiently large number of consecutive beats in each patient. In addition, analyses have been based predominantly on data pooled from numerous patients and often have involved derived indirect indexes of left ventricular performance. These studies also have not addressed the potential differences in analysis due to different underlying disease states or the degree of basal left ventricular dysfunction.

In clinical practice, global left ventricular ejection fraction usually is obtained from contrast ventriculography by analysis of a single beat, or at most from 3 to 5 beats, even in patients with atrial fibrillation. With use of multigated equilibrium radionuclide angiocardiography, left ventricular ejection fraction is calculated from the summation of several hundred individual cardiac cycles. Because of the marked beat-to-beat variation, the applicability of these approaches to patients with atrial fibrillation has been questioned. In the present study, left ventricular ejection fraction was evaluated with the computerized nuclear probe, an instrument with sufficiently high sensitivity to allow beat-to-beat assessment of the radionuclide time-ac-

tivity curve.[9–11] With use of a multichannel strip chart recorder, the left ventricular volume curve can be displayed in synchrony with the electrocardiogram. This allows calculation of beat-to-beat left ventricular ejection fraction and relative left ventricular volumes, which can be related directly to cycle lengths. This approach has been used in this laboratory, as well as by other investigators,[9,11,12] to assess the left ventricular functional responses to atrial and ventricular premature beats.

The goals of this study were (1) to determine the beat-to-beat variability of left ventricular ejection fraction in atrial fibrillation and relate individual beat measurements to mean values obtained by averaging multiple beats, and (2) to use this beat-to-beat analysis to evaluate some of the potential control mechanisms operative in atrial fibrillation. From a clinical perspective, this analysis should provide relevant insights concerning the utility of the ejection fraction measurement in atrial fibrillation.

Methods

Patient group: Eighteen patients with atrial fibrillation were studied. Three additional patients were excluded because of excessive respiratory motion or concomitant premature ventricular beats, or both. In all cases, patients had a stable rhythm of atrial fibrillation for at least 3 months before the study. The mean age was 67 years (range of 53 to 90). Twelve patients were men and 6 women. The primary etiologic diagnosis was determined with clinical evaluation and both M-mode and 2-dimensional echocardiography in all patients (Table I). Cardiac catheterization data also were available in 5 patients. Patients were classified into 3 groups on the basis of the primary diagnosis: (1) mitral stenosis (5 patients), (2) mitral regurgitation (6 patients), and (3) coronary artery disease (7 patients). In group 3, all 7 patients had previous myocardial infarction; none were unstable at the time of the study or had any clinical evidence of associated mitral regurgitation. The mean heart rate determined over approximately 1 minute in each patient was 69 beats/min with a range of 52 to 100 beats/min. All patients were receiving digitalis for control of ventricular response. Thus, only patients with relatively slow heart rates were studied. Three patients had a history of congestive heart failure and were taking diuretic drugs. No patient was receiving calcium slow channel antagonists.

Patient protocol: All patients were studied with the computerized nuclear probe (Bios, Valhalla, New York) in the supine position after technetium-99m in vivo blood pool labeling (25 mCi). The nuclear probe was positioned over the left ventricular and background regions of interest using algorithms and operator routines previously described.[9] Patients breathed shallowly during data acquisition. The analog output from the nuclear probe was interfaced with a multichannel strip chart recorder (Elema-Schonander Mingograph 34, Solna, Sweden). This allowed continuous display and permanent recording of a simultaneously acquired left ventricular time-activity curve, background activity level, and electrocardiographic signal (Fig. 1). After final probe positioning and confirmation of patient stability, beat-to-beat data were acquired for approximately 1 minute; 50 consecutive beats then were identified for subsequent analysis. As previously described, relative end-diastolic, end-systolic, and stroke volumes and ejection fraction were calculated manually for each beat.[9] Each beat was measured twice and the mean used for analysis.

There are potential problems with the use of radionuclide techniques for assessment of left ventricular performance in atrial fibrillation. In patients with an enlarged left atrium, left atrial radioactivity may contribute to the left ventricular time-activity curve and may artifactually decrease the calculated left ventricular ejection fraction. However, with the probe, particular care was taken to assure adequate caudal tilt, minimizing left atrial-left ventricular overlap. In addition, determination of the optimal left ventricular and background positions with the computer-derived algorithms is more difficult in patients with marked beat-to-beat fluctuations in stroke volume. This occurs because the positioning algorithms are based on beat-to-beat changes in stroke counts and average counts.[9–11] Particular care was taken to move the probe slowly allowing the algorithms to average more beats in each position. This technique also has been used successfully to study the effects of atrial and ventricular premature beats.[11,12]

In 14 patients, multiple gated equilibrium cardiac blood pool imaging was performed within 30 minutes of the initial

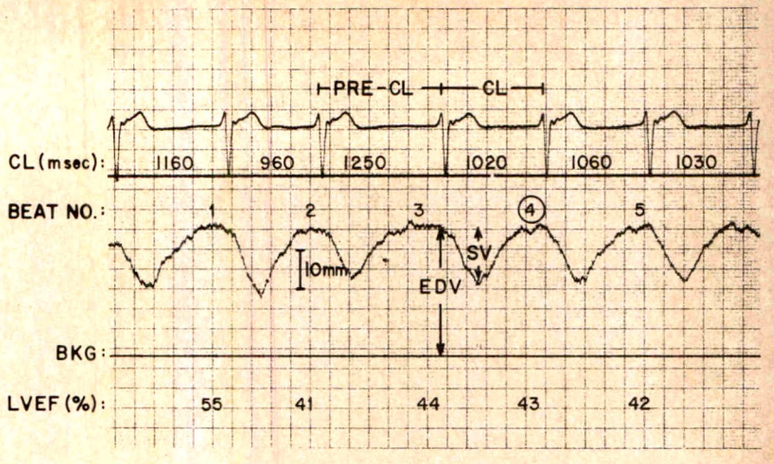

FIGURE 1. Actual beat-to-beat data obtained with the computerized nuclear probe. The data are displayed on the stripchart recording showing the electrocardiogram, the radionuclide time-activity curve, and the background (BKG) activity level. Beat-to-beat values for cycle length (CL) and ejection fraction are shown for 5 consecutive beats. Beat 4 is the beat in question (**circled**). The immediately preceding cycle length is 1,020 ms, whereas the second preceding cycle length is 1,250 ms. Stroke volume (SV) and end-diastolic volume (EDV) are derived directly from the stripchart recording. LVEF = left ventricular ejection fraction.

nuclear probe study.[13] Data were acquired in the left anterior oblique position providing the optimal separation of right and left ventricles and with 10° to 15° caudal tilt. Data were acquired for 8 to 10 minutes with a portable gamma camera and minicomputer (Technicare VIP 450, Solon, Ohio). All beats were accepted; there was no rejection of beats with excessively long- or short cycle lengths. Left ventricular ejection fraction was calculated using a variable region of interest and quadrant threshold edge definition (Q-MICA program). The remaining 4 patients did not undergo multiple gated blood pool imaging for logistic reasons.

Statistical analysis: Group data are presented as the mean ±1 standard deviation, unless otherwise indicated. Comparisons within individual patients were made by the paired *t* test. Linear (univariate and multivariate), polynomial, and exponential regression equations and correlation coefficients were determined with use of standard formulas. Only significant ($p < 0.05$) correlation coefficients are included in the tables.

In the manual analysis of each probe study, the mean and standard deviation of the 50 consecutive beats were determined for stroke counts (measured in millimeters), end-diastolic counts (millimeters), end-systolic counts (millimeters), and left ventricular ejection fraction (stroke counts divided by end-diastolic counts × 100) (Fig. 1). The mean value for ejection fraction in the 50 beats was used for comparisons with multigated blood pool studies.

On the basis of our previously published data, the absolute variability of beat-to-beat left ventricular ejection fraction measurements was ±5.8% (expressed as ±2 standard deviations in ejection fraction units).[9] These data were derived from 10 beats each in 71 patients with normal sinus rhythm. There was no significant difference in patients with normal and abnormal mean ejection fractions. In each patient in the present study, the mean ejection fraction ±6% was calculated; this range then defined the expected intrinsic variability for a given patient assuming sinus rhythm. Individual beats with ejection fractions that fell outside this range were considered to be significant outliers.

Correlation coefficients were derived based on the 50 consecutive beats in each patient. Beat-to-beat data for the overall group of 18 patients were not pooled. Left ventricular performance (both ejection fraction and relative stroke volume) was related to cycle length by a linear regression equation, an exponential regression equation, and up to a fourth order polynomial regression equation. In all instances, the linear regression equation resulted in the highest consistent correlation coefficient. Therefore, all subsequent analyses only involved the linear equations. Stepwise multiple linear regression equations then were obtained relating left ventricular performance to both the cycle length immediately preceding the beat in question and the second preceding cycle length, that is, 2 beats before the beat in question.[14] This allowed determination of the effects of abrupt alterations in cycle length on ventricular function. This approach also has been used in previous studies of atrial fibrillation.[5–7] The potential role of end-systolic volume in addition to preceding cycle lengths also was assessed by stepwise multiple linear regression analysis.

Results

In the overall group of 18 patients with atrial fibrillation, the mean left ventricular ejection fraction obtained with the probe ranged from 17 to 51% (Table I). The mean (±1 standard deviation) left ventricular ejection fraction in the 3 patient subgroups averaged as follows: (1) mitral stenosis (47 ± 3%, n = 5); (2) mitral regurgitation (39 ± 11%, n = 6); and (3) coronary artery disease (35 ± 12%, n = 7). Six patients had markedly abnormal left ventricular performance (mean left ventricular ejection fractions less than 40%): 2 with mitral regurgitation and 4 with coronary artery disease.

There was substantial beat-to-beat variation in cycle length and left ventricular ejection fraction in all patients. For the overall group of 18 patients, the pooled standard deviation of beat-to-beat ejection fraction based on a total of 900 individual cardiac cycles was 6.9%, which is more than twice the value for normal sinus rhythm (2.9%).[9] Thus, using ±2 standard deviations (accounting for 95% of variability), a mean ejection fraction value generally would be derived from individual beats with ejection fractions both greater and lesser by 14%. For example, a mean ejection fraction of 40% could be expected to be derived from beats as low as 26% and as high as 54%. This was apparent in each disease subgroup, as well as in those with mean ejection fractions below 40% and those with ejection fractions between 40 and 51% (Fig. 2 and 3). On the basis of the analysis of 50 beats in each patient, 32 ± 7 individual cardiac cycles had ejection fractions within the range derived from the mean and expected variability. Of the beats falling outside this range, there was an equal distribution above and below the outer limits (9 ± 3

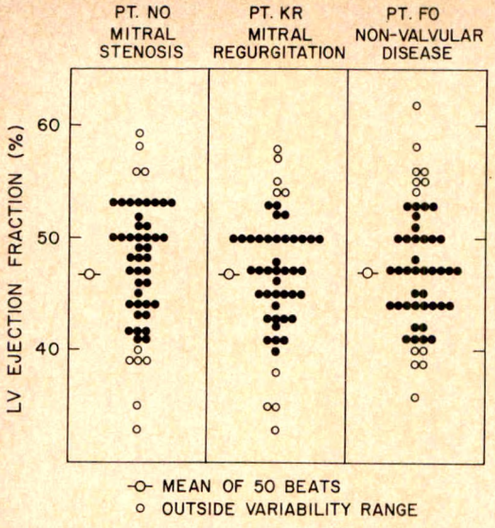

FIGURE 2. Beat-to-beat left ventricular (LV) ejection fraction in 3 patients with atrial fibrillation and mean ejection fraction of approximately 47%. Left ventricular ejection fraction is shown for 50 consecutive beats in each patient. The beats falling within the variability range (see text) are indicated by **closed circles.** The beats falling outside the variability range are shown as **open circles.** Note that in each disease state there is marked beat-to-beat variability in ejection fraction, with a substantial number of beats falling both above and below the limits of variability.

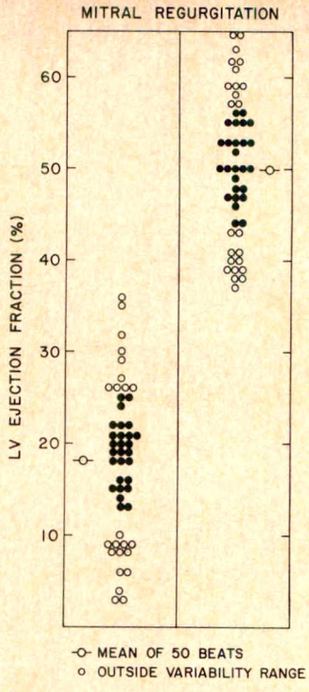

FIGURE 3. Beat-to-beat left ventricular ejection fraction in 2 patients with mitral regurgitation. One patient (**left panel**) had marked left ventricular dysfunction, whereas the other patient (**right panel**) had relatively preserved left ventricular (LV) performance. There is marked beat-to-beat variability in left ventricular ejection fraction in both patients. The format is the same as in Figure 2.

beats versus 10 ± 3 beats, p = not significant [NS]). In individual patients, 8 to 28% (mean 18%) of individual beats exceeded the variability range, whereas 6 to 32% (mean 19%) fell below the variability range (Table I). This beat-to-beat variation occurred independent of underlying disease (mitral valvular or coronary artery disease) and the level of baseline global left ventricular function. Specifically, there was no relation between the number of outliers and the mean ejection fraction (p = NS).

In the 14 patients who underwent both a nuclear probe study and multiple gated blood pool imaging, there was no significant difference in mean probe and gated camera ejection fractions (39 ± 11% versus 41 ± 10%, p = NS). The mean interstudy difference was 4 ± 1%. In no instance did the 2 values differ by more than 9%. There was excellent agreement between mean ejection fraction derived from the nuclear probe and gated ejection fraction obtained by gamma camera imaging (r = 0.90, p <0.001) (Fig. 4). This close relation may not persist at higher heart rates (>100 beats/min), when the systolic ejection time may vary substantially. Thus, the ejection fraction derived from the electrocardiographically gated summed time-activity curve is a relevant index of mean beat-to-beat ejection fraction in atrial fibrillation. However, there is substantial beat-to-beat variation, casting doubt on the clinical utility of analyses based only on 1 beat or a few beats.

By assessment of the dependence of left ventricular function on loading conditions, specifically end-diastolic volume and preceding cycle lengths, the relative roles of the Frank-Starling mechanism[15,16] and the interval-strength relations[17,18] were addressed (Table II). On a beat-by-beat basis, left ventricular ejection fraction correlated positively with cycle length in each patient (Frank-Starling effect) (Fig. 5). In patients with mitral stenosis (Group I), the correlation coefficient ranged

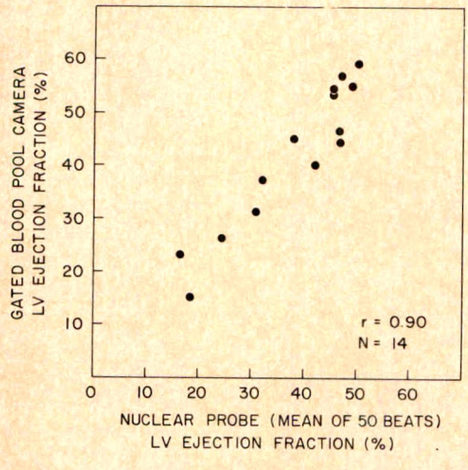

FIGURE 4. Left ventricular (LV) ejection fraction derived from gated blood pool imaging and from the mean of 50 beats obtained with the computerized nuclear probe. Note the excellent correlation between values derived from each technique. There is no systematic under- or overestimation with the probe (camera ejection fraction = 1.1 [probe ejection fraction] + 1.8).

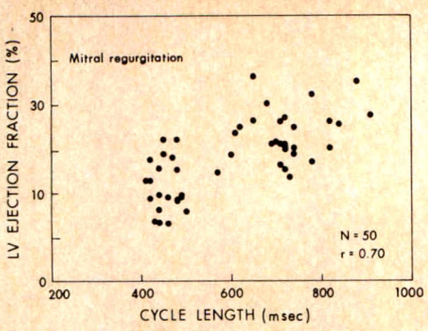

FIGURE 5. Dependence of left ventricular (LV) ejection fraction on cycle length in a patient with mitral regurgitation. Fifty consecutive beats were analyzed in this patient. Note the correlation between left ventricular ejection fraction and beat-to-beat cycle length.

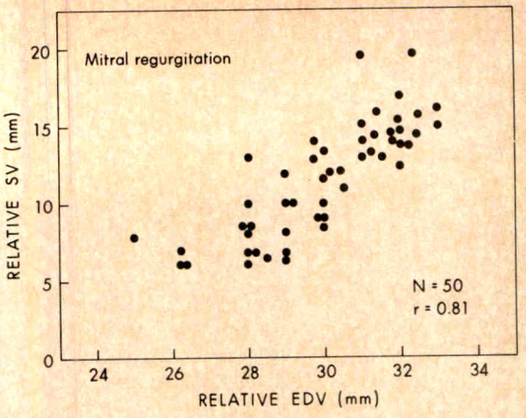

FIGURE 6. Dependence of relative stroke volume on relative end-diastolic volume (EDV) in a patient with mitral regurgitation. This is a demonstration of the Frank-Starling effect. Larger end-diastolic volumes are associated with larger stroke volumes (SV).

from 0.51 to 0.59. In patients with mitral regurgitation (Group II), the correlation coefficient ranged from 0.38 to 0.82. In patients with coronary disease (Group III), the correlation coefficient ranged from 0.50 to 0.81. By applying the multiple linear regression analysis, the additive effects of including the second preceding cycle length were assessed (Table II). This allowed evaluation of whether the intervals between preceding beats had direct effects on the left ventricular contractile state (interval-strength relation). All 6 patients with mitral regurgitation demonstrated significant multiple correlation coefficients when the second preceding cycle length was taken into account. The multiple correlation coefficients now ranged from 0.55 to 0.89. However, in each case, the added coefficient was negative; that is, there was a significant inverse relation between ejection fraction and the second preceding cycle length. In direct contrast, the added factor was not significant in any of the patients with mitral stenosis (Group I). There was a variable response in the patients with nonvalvular disease, with only 2 of 7 patients demonstrating significant multiple correlation coefficients. These 2 patients had the lowest ejection fractions (17 and 26%) in the group. Relative end-systolic volume in the preceding beats was not a significant factor in addition to preceding cycle lengths.

Stroke volume correlated significantly with immediately preceding cycle length in all patients and with end-diastolic volume in all except 1 patient with coronary artery disease and a low ejection fraction (11%) (Fig. 6). Once again, addition of the second preceding cycle length resulted in significantly improved correlation coefficients for all patients with mitral regurgitation but only 2 of 7 patients with coronary disease. None of the patients with mitral stenosis had significant interaction of the second preceding cycle length and global left ventricular performance (Table II).

Discussion

This radionuclide study clearly demonstrates that no single value for left ventricular ejection fraction adequately characterizes left ventricular function in atrial fibrillation. In each patient, there was a substantial number of cardiac cycles in which left ventricular ejection fraction exceeded the mean value. The mean left ventricular ejection fraction may substantially underestimate beat-to-beat left ventricular function in the resting state—by as much as 14% in ejection fraction units using mean data. However, there was good agreement between average left ventricular fraction obtained by electrocardiographically gated equilibrium blood pool imaging and the mean of beat-to-beat function obtained with the nuclear probe; this agrees with a previous study in which a nonimaging probe was used.[19] All patients in this study were receiving digitalis, and this may have impact on our findings. The wide fluctuations in cycle length in atrial fibrillation may result in distortion of the gated time-activity curve. The major differences in the configuration of the left ventricular volume curve occur during diastole, with shortening of the mid to late diastolic phases. As heart rate increases, the duration of diastasis decreases and the configuration of the diastolic curve changes.

The present study evaluated the presence and role of the Frank-Starling mechanism[15,16] and the interval-strength relation[17,18,21] in determining beat-to-beat left ventricular performance in atrial fibrillation (Table II). The significant correlations between either ejection fraction or stroke volume and cycle length are consistent with the Frank-Starling mechanism. Thus, a longer cycle length (slower heart rate) results in a higher level of left ventricular performance. Furthermore, the significant correlation between stroke and end-diastolic volumes in all but 1 patient is further evidence for the Frank-Starling relation. This major dependence of ejection fraction on preload occurred in all 3 patient groups over a broad range of basal ejection fractions. This interaction also should occur in patients with normal sinus rhythm. The optimal characterization of this relation was derived using a linear regression analysis. Although a nonlinear phase has been shown experimentally,[16] neither a polynomial regression equation up to the fourth order nor a exponential equation resulted in a consistently better relation in these patients.

If the Frank-Starling mechanism were the only determinant of left ventricular performance in atrial fibrillation, then one would expect an extremely close relation between cycle length and ejection fraction in a given patient. However, significant correlation coefficients ranged from 0.38 to 0.82, with only 8 of 18 patients having correlation coefficients greater than 0.70. The direct role of changes in afterload could not be assessed in this study, because aortic pressure and systemic vascular resistance were not measured on a beat-to-beat basis. However, the interval-strength relation appeared to be operative in all patients with predominant mitral regurgitation. In each instance, linear regression analysis involving not only the cycle length but also the preceding cycle length resulted in a significantly improved correlation, although the dependent variables had opposing effects. This suggests that the systolic phase of left ventricular contraction is modulated by 2 independent processes in mitral regurgitation. The interval between preceding beats appears to have a direct effect on the contractile state of the left ventricle 2 beats later, causing a change in systolic force development. These findings agree in concept with those in previous studies.[4–7]

In contrast to mitral regurgitation, no patient with mitral stenosis had evidence of a significant interval-strength relation. Because a substantially smaller proportion of diastolic filling takes place in early diastole in mitral stenosis than in regurgitation, the duration of left ventricular filling may be of more importance in determining left ventricular function in mitral stenosis than in regurgitation. In this case, the Frank-Starling mechanism would appear to predominate. In coronary disease, the interval-strength relation only appears to be present in 2 patients with severe left ventricular dysfunction.

Previous studies of atrial fibrillation have employed a variety of techniques.[1–7] These analyses have been limited in that left ventricular ejection fraction and volumes could not be determined in an adequately large number of consecutive beats in each patient, including those with regional dyssynergy. These studies, as well as those in conscious instrumented baboons[15] have suggested that the Frank-Starling mechanism was the major determinant of left ventricular function. The data from the present study confirm these results and furthermore suggest that in patients with mitral regurgitation the interval-strength relation also plays an important role in determining left ventricular performance. Future studies with the nuclear probe will not be limited to ejection phase indexes of left ventricular function and volumes but will include a detailed assessment of diastolic function, as well as pressure-volume relations in atrial fibrillation.[22]

Comparative Effects of Beta-Adrenergic Blocking Drugs On Experimental Ventricular Fibrillation Threshold

JEFFREY L. ANDERSON, MD, HUGO E. RODIER, BA, and LARRY S. GREEN, MD

Recent clinical studies suggest that certain beta-adrenergic blocking drugs, such as timolol, may reduce sudden death in patients with ischemic heart disease, but the mechanism has not been established. To assess and compare antifibrillatory effects of beta-blocking drugs as a potential mechanism of sudden death prevention, the ventricular fibrillation (VF) threshold was measured in anesthetized, open-chest dogs before and after 3 minutes of coronary ischemia during intravenous administration of saline solution or 3-fold serial increments (0.003 to 1.0 mg/kg) of 5 beta-blocking drugs with various accessory properties. Ventricular fibrillation occurred in control studies after delivery of a current train of 11.7 ± 7.6 mA in the nonischemic state and 7.0 ± 7.4 mA during ischemia (n = 46). All 5 beta-blocking drugs but not saline solution caused substantial (average 6-fold) increases ($p < 0.001$) in the VF threshold under both nonischemic (to 67 ± 30 mA) and ischemic conditions (to 42 ± 31 mA). The maximal VF thresholds attained were similar for individual drugs: timolol, 71, 39 mA (nonischemic, ischemic conditions, n = 10); pindolol, 81, 46 mA (n = 7); propranolol, 58, 36 mA (n = 7); metoprolol, 60, 40 mA (n = 7); and labetolol, 67, 52 mA (n = 6). The effective doses (mg/kg) at which maximal effects first occurred, however, varied widely: timolol, 0.01 mg/kg; pindolol, 0.1 mg/kg; propranolol, 0.3 mg/kg; metoprolol, 1.0 mg/kg; and labetolol, 1.0 mg/kg. The antifibrillatory potency (mg/kg) generally paralleled known ratios of beta-blocking efficacy, except for timolol's apparently greater potency. Interruption of stellate ganglionic impulses accounted for part of the augmentation in VF threshold. Thus, a substantial antifibrillatory effect accompanies experimental blockade of beta-adrenergic stimuli. An increase in VF threshold is suggested as a possible protective mechanism by which beta-blocking drugs reduce sudden death.

Sudden cardiac death has been termed the major challenge confronting contemporary cardiology.[1] Ventricular fibrillation (VF) occurring during usual daily activities in patients with underlying coronary artery disease is the precipitating cause in most patients.[1–4] Unfortunately, treatment with standard and also newer class I antiarrhythmic agents has not yet been shown effective.[4–8] The possibility that certain beta-adrenergic blocking agents (antiarrhythmic class II) might decrease cardiac death, particularly sudden cardiac death in postinfarction patients, was initially suggested by studies dating back almost a decade.[9,10] Recently, a carefully designed and controlled study in patients with myocardial infarction has demonstrated the ability of timolol to reduce sudden cardiac death by approximately 45% over a 2-year period.[11] On the basis of this study, timolol has been approved by the Food and Drug Administration for prophylaxis of cardiac death in patients with recent infarction. Whether this protective effect is specific to certain agents such as timolol or a general effect of the beta-adrenergic blocking agents has not been established. Beneficial effects of other beta-adrenergic agents such as metoprolol and propranolol have been suggested by subsequently reported studies.[12,13]

Despite this clinical evidence for a cardioprotective effect of at least certain beta-adrenergic blocking agents, the mechanism of action remains obscure. An antiischemic effect is well established; however, most episodes of sudden cardiac death are unassociated with excessive cardiac demand, history of anginal acceleration, or myocardial infarction.[1] Even transient decreases

in coronary flow however, may be associated with decreases in VF threshold in animal models.[1,14] Platelet aggregation and coronary spasm have been proposed as mechanisms causing transient coronary hypoperfusion.[15,16] Propranolol has weak antiplatelet activity,[17] but this has not been shown to be clinically important. Aspirin, an established antiplatelet drug, does not reduce sudden cardiac death in coronary patients.[18] Beta-blocking drugs are ineffective against coronary spasm and may in fact exacerbate vasotonic angina.[19] An antiarrhythmic effect (suppression of ventricular ectopy) also appears unsatisfactory as a single mechanism because beta-blocking drugs show relatively weak antiectopic activity in comparison with class I drugs.[20] However, a beneficial effect of these agents on VF threshold is a potential mechanism of action that has been inadequately explored.[21] Little is known about the experimental antifibrillatory effects of beta-adrenergic blocking drugs, and no information is available on comparative effects among these agents.

This study was designed to assess the importance of antifibrillatory effects of the beta-adrenergic blocking drugs in a previously validated canine model.[22] The study was designed to address several questions: What quantitative effects on VF threshold occur, and what is the nature of the dose-response curve? Are any antifibrillatory effects agent- or class-specific?[23] Are accessory drug characteristics of importance in determining antifibrillatory potential?[24,25] Are effects explained by interruption of cardiac sympathetic stimulation?

Methods

Mongrel dogs of both sexes, weighing 15 to 25 kg, were anesthetized with pentobarbital sodium (30 mg/kg), intubated, and artificially ventilated with room air. Electrocardiographic limb leads were attached and monitored continuously on an oscilloscope. A cutdown was performed on a femoral artery and vein, an arterial pressure line established for blood pressure monitoring, and a venous infusion catheter placed for crystalloid and drug administration. The chest was opened using cautery and shears and the heart isolated and suspended in a pericardial cradle. Bipolar epicardial hook electrodes were placed in the right atrium and right ventricle (outflow tract). The sinus node was crushed and atrioventricular sequential pacing (cycle length 400 ms) initiated. Internal defibrillator leads were inserted into the left ventricular apex and the right atrial appendage and secured with pursestring sutures. Pacing studies were performed with the use of a custom 4-channel programmable stimulator coupled to a multichannel oscilloscope and recorder. The left anterior descending coronary artery was dissected free in its midportion and a lubricated umbilical tape tunneled underneath. The umbilical tape could then be used to temporarily occlude the vessel. A stainless steel, bipolar hook electrode with interelectrode separation of 3 mm was attached epicardially at the right ventricular septum, bordering the potential ischemic zone, and used to deliver the VF pulses. A bipolar plunge electrode was placed through the left ventricular mid-anterior wall 5 cm from this electrode.

Determination of VF threshold: This determination was performed with modification of a previously described method.[14,22,26] Animals were paced from the atrium at a constant cycle length of 400 ms. Four millisecond fibrillation pulses of 60 Hz frequency and 180 ms total duration were synchronized to the atrioventricular pacing stimuli so as to scan the T wave in the vulnerable period of the heart. The same delay after the basic drive stimulus (100 to 150 ms) was used throughout testing in any 1 animal. Current delivered was measured exactly by recording voltage decrease across a precision 1,000 Ω resistor in series with the electrodes. Current intensity was increased in 0.5 mA increments to 5 mA, 1 mA increments to 10 mA, 2 mA increments to 20 mA, 5 mA increments to 50 mA, and 10 mA increments to 100 mA, or until ventricular fibrillation developed. Stimulus trains were delivered after every ninth basic drive cycles, and 3 trains were delivered at each current level. The current intensity inducing sustained VF was defined as the VF threshold. When VF occurred, the heart was immediately defibrillated using a capacitor discharge direct current impulse of 15 J applied through the internal defibrillator leads. The heart was allowed to recover for a minimum of 15 minutes.

The schedule for determination of VF threshold was as follows: Before drug administration, a control determination was made in the absence of ischemia. After a 15-minute rest interval, the mid-anterior descending coronary artery was occluded and threshold determinations during ischemia ("ischemic thresholds") made after 3 minutes. The ligature was released and the heart promptly defibrillated. An initial dose of drug (or saline solution) was administered and VF thresholds repeated without and with ischemia, beginning at 15 minutes. The second and subsequent serial dilutions of drug (or saline solution) were administered and testing repeated in a similar fashion. Normal saline solution was infused at a rate sufficient to maintain blood pressure in the range of pre-drug control readings over the period of study. In several animals, the decay kinetics of elevations in VF threshold were explored by further determinations 1 and 2 hours after the final dose of drug.

Repetitive ventricular response threshold: The currents at which 2 and >2 premature complexes were elicited by the fibrillation pulse were defined as the thresholds for single and multiple repetitive ventricular responses.

Ventricular effective refractory period: The left ventricular effective refractory period was defined as the longest premature interval at which a single premature impulse consistently failed to cause ventricular depolarization. Premature stimuli (S_2) were introduced at twice diastolic threshold after every third paced beat through the plunge bipolar electrode in the left ventricle. Refractory periods were determined to the nearest 1 ms. Evaluations were made just before determinations of VF threshold. Ventricular activation times were measured as the time interval from onset of pacing artifact introduced through the left ventricular plunge electrode to that recorded in the right ventricular electrode 5 cm distant, as measured on a strip chart, paper speed 200 mm/s.

Drug testing: Five beta-adrenergic blocking agents with differing accessory properties (Table I) were selected for study and obtained from commercial sources: timolol (Merck, Sharp and Dohme, West Point, Pennsylvania), pindolol (Sandoz, East Hanover, New Jersey), propranolol (Ayerst, New York, New York), metoprolol (Geigy Pharmaceuticals, Summit, New Jersey), and labetolol (Shering, Bloomfield, New Jersey). Drugs were solubilized and buffered to a physiologic pH when necessary and diluted in normal saline solution to allow convenient administration of doses of 0.003 to 1.0 mg/kg. Doses were calculated on the basis of an average animal weight of 20 kg. Increments of 0.003, 0.01, 0.03, 0.1, 0.3, and 1.0 mg/kg were used. Drugs were typically administered in volumes of 1 to 25 ml. Control animals were given an equivalent volume dose of saline solution at each dosing time.

TABLE I Pharmacologic Properties of Some Beta-Blocking Drugs*

Drug	Membrane Stabilizing	Cardio-selectivity	Partial Agonist	Alpha-Blocking
Propranolol	++	0	0	0
Timolol	0	0	±	0
Metoprolol	±	+	0	0
Pindolol	+	0	+++	0
Labetolol	+	0	0	+

* Modified from Frishman.[24]
0, +, ±, ++, +++ = range of drug effect intensity, where 0 = no effect and +++ = very strong effect.

Stellate ganglionectomy: In selected animals, both right and left stellate ganglia were identified near the apex of each pleural cavity and dissected free. After control VF threshold determinations, all branches of each ganglion were transected and the ganglia removed. Determinations were repeated. Timolol, 0.01 mg/kg, was administered and the VF threshold determined again.

Analysis of data: Electrophysiologic variables were averaged and are presented as mean ± standard deviation for each separate group of animals. Differences in mean responses between 2 groups were analyzed with Student's *t* test. Analysis of variance was used to assess differences among 3 or more data sets. Paired *t* testing was used to compare responses in the same animal under 2 different conditions. Significance was assumed at a probability (p) level of <0.05 for 2-tailed hypotheses. For purposes of analysis, a VF threshold of 110 mA was assigned in cases in which the measurable threshold (100 mA) was exceeded.

Results

Control VF thresholds: Ventricular fibrillation threshold averaged 11.7 ± 7.6 mA in 46 animals during control nonischemic testing. During control ischemic testing, the average fibrillation current was reduced to 7.0 ± 7.4 mA ($p < 0.01$ versus nonischemic).

VF threshold response over time (saline control): Nine animals subsequently given saline solution alone showed a flat VF threshold response with time, during both nonischemic and ischemic conditions (Fig. 1, Table II).

VF threshold response to timolol (Fig. 1, Table II): In contrast, VF thresholds were augmented substantially after as little as 0.003 mg/kg timolol in 10 dogs and increased further after 0.01 mg/kg to 71 ± 33 mA for nonischemic and 38 ± 37 mA for ischemic conditions, representing 3- to 6-fold increases. The large standard deviations point to substantial animal-to-animal variation in response. However, differences after 0.01 mg/kg for nonischemic threshold compared with predrug control values or to the saline response at a similar time point were highly significant ($p < 0.001$). Threshold increases during ischemia were significant in comparison with saline solution and pre-drug control at levels of $p < 0.01$ and $p < 0.05$, respectively.

VF threshold response to pindolol (Fig. 1, Table II): A substantial increase in VF threshold occurred after pindolol in 7 dogs, and these increases were highly significant. A maximal response was achieved at a dose of 0.1 mg/kg; the VF threshold averaged 81 ± 32 mA without and 46 ± 31 mA with ischemia, a 7-fold or greater increase. These peaks differed significantly from concurrent saline solution ($p < 0.001$) and from initial predrug control responses ($p < 0.005$ for nonischemic and $p < 0.02$ for ischemic conditions).

Response of VF threshold to propranolol (Fig. 2, Table II): After propranolol, VF threshold in 7 animals increased more gradually than after timolol or pindolol to plateau after 0.3 mg/kg at 58 ± 27 mA without and 36 ± 11 mA with ischemia, a 5-fold or greater increase. Differences between peak values and initial control measurements ($p < 0.01$, $p < 0.001$) and parallel saline controls ($p < 0.002$, $p < 0.001$) were highly significant under both nonischemic and ischemic conditions, respectively.

Response of VF threshold after metoprolol (Fig. 2, Table II): The response of VF threshold after metoprolol in 7 animals is given in Figure 2. VF threshold continued to increase until after doses of 0.3 to 1.0 mg/kg. After 1 mg/kg, threshold averaged 60 ± 28 mA

TABLE III Summary of Optimal Doses of Beta-Blocking Drugs

Drug	VFT (mg/kg)	Beta-Blockade Potency Ratio[24]
Timolol (n = 10)	0.01	6
Pindolol (n = 7)	0.1	6
Propranolol (n = 7)	0.3	1 (0.2 mg/kg)
Metoprolol (n = 7)	1.0	1
Labetolol (n = 6)	1.0	0.3

VFT = ventricular fibrillation threshold.

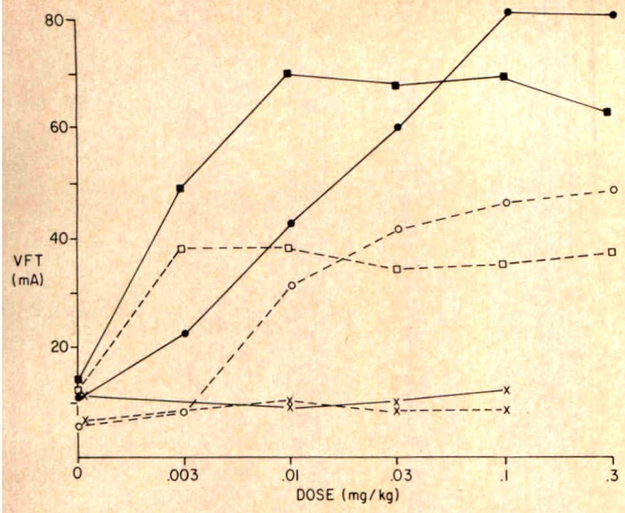

FIGURE 1. Effects on ventricular fibrillation threshold (VFT) of incremental dosing with timolol (**squares**), pindolol (**circles**), or saline solution (**X**). The VF threshold in milliamps is shown on the vertical axis and the drug dose (for timolol, pindolol) on the horizontal axis; the response to drug is compared with time-concurrent saline controls. Measurements during ischemia are represented by **open symbols connected by dashed lines**. Those without ischemia are represented by **solid symbols and lines**. See Table II and text for additional details.

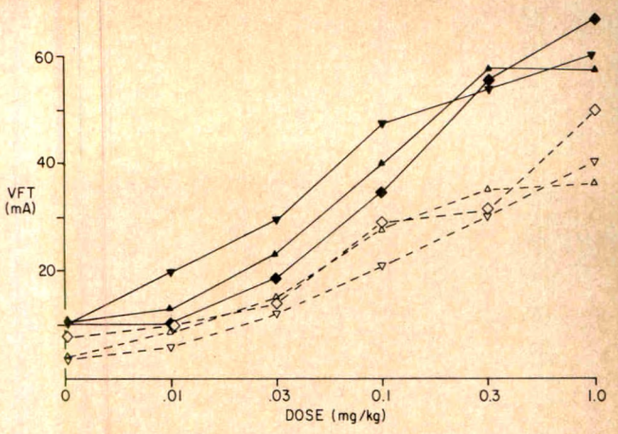

FIGURE 2. Effect on ventricular fibrillation threshold (VFT) of incremental dosing with labetolol (**diamonds**), metoprolol (**wedges**), and propanolol (**triangles**). The format is similar to that in Figure 1, except that saline controls are not redrawn.

without and 40 ± 43 mA with ischemia, a ≥6-fold increase. Again, interanimal variation was great, particularly during ischemia. Differences between drug and saline responses were significant at $p < 0.001$ for nonischemic and $p < 0.02$ for ischemic conditions. The nonischemic value differed from its initial control at a level of $p < 0.02$.

Response of VF threshold to labetolol (Fig. 2, Table II): Labetolol caused increases in VF threshold after approximately 0.1 mg/kg. After 1 mg/kg, VF threshold averaged 67 ± 36 mA without and 52 ± 34 mA with ischemia, a 6-fold increase. The peak effect differed from concurrent saline control at significance levels of $p < 0.001$ and $p < 0.01$ (nonischemic, ischemic conditions) and from initial control values at $p < 0.02$.

Summary of beta-blocker effects on VF threshold (Tables II and III): Each beta-blocking drug augmented VF threshold to similar maximal levels, averaging 67 ± 30 mA without and 42 ± 31 mA with ischemia, a 6-fold increase (Table II). However, the doses at which optimal effects were achieved varied widely. The order of potency generally paralleled that of known beta-blocking potency (Table III). Also, maximal effects were generally achieved at doses known to provide full beta-blockade. However, it can be noted that timolol caused maximal effects at lower apparent relative doses, for example, at one tenth that of pindolol, which is said to have equivalent beta-blocking potency.[24]

Response of VF threshold during stellate ganglionectomy: In 3 animals, bilateral stellate ganglion resection led to variable increases in VF threshold (Fig. 3). Subsequent administration of timolol (0.1 mg/kg) led to further modest to substantial increases in VF threshold, to levels provided by the beta-blocking drug alone (compare with Figure 1).

Repetitive ventricular response thresholds (Table IV): Increases in repetitive responses paralleled those in VF threshold. Thresholds for appearance of multiple nondriven repetitive ventricular responses (m-RVR) increased 6-fold after optimal doses of beta-blocking drugs for both nonischemic and ischemic conditions but did not change after saline solution. Differences in drug versus saline response were significant ($p < 0.001$, $p < 0.05$). Nonischemic m-RVR threshold averaged 8.6 mA before and 53.8 mA after therapy ($p < 0.001$). During ischemia, m-RVR threshold averaged 5.6 mA before and 35.9 mA after therapy ($p < 0.001$). Increases in m-RVR threshold also reached significance during nonischemic and ischemic conditions for each individual drug.

Thresholds for appearance of single nondriven repetitive ventricular response (s-RVR) increased 8- to 10-fold after optimal doses of beta-blocking drugs

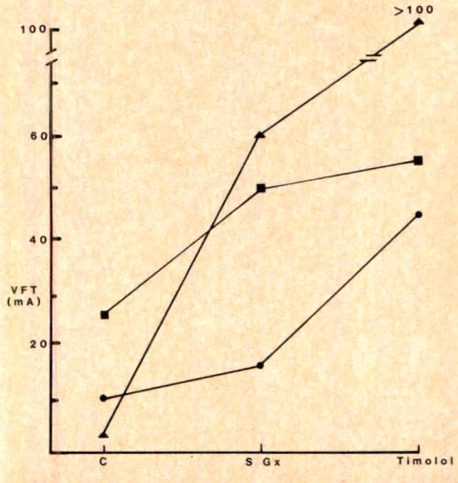

FIGURE 3. Effects of sequential bilateral stellectomy and beta blockade with timolol, 0.1 mg/kg, in 3 dogs. C = control study; SGX = stellate ganglionectomy. VFT = ventricular fibrillation threshold.

TABLE IV Therapeutic Effects on Repetitive Ventricular Response Thresholds

‡ $p < 0.001$ versus predrug.
§ $p < 0.05$ versus 25 ml saline solution.
‖ $p < 0.01$ versus 25 ml saline solution.
¶ $p < 0.001$ versus 25 ml saline solution.
s-RVR = single, multiple repetitive ventricular responses.

(Table IV). Nonischemic single-RVR thresholds averaged 2.3 mA before and 27.4 mA after therapy ($p < 0.001$). Responses during ischemia were similar. Increases in s-RVR threshold were also significant for each individual drug. In the saline control group, small increases with repeated testing were noted, but comparisons of saline versus drug therapy at similar times showed significant differences for both ischemic and nonischemic conditions ($p < 0.02$).

Time-decay in augmentation of VF threshold and m-RVR: One hour after the final beta-blocking drug dose, VF thresholds had declined by 14.0 ± 19.6 mA ($p < 0.005$, n = 23 pair) for nonischemic and by 11.4 ± 21.8 mA ($p < 0.05$, n = 20 pair) for ischemic conditions. After 2 hours, VF threshold had decreased an average of 25.4 ± 22.0 mA ($p < 0.001$, 17 pair) for nonischemic and 18.3 ± 28.0 mA ($p < 0.02$, 16 pair) for ischemic conditions. One hour after the final beta-blocking drug dose, multiple-RVR threshold had declined by 12.3 ± 20.3 mA ($p < 0.02$, n = 20 pair) for nonischemic and 9.6 ± 19.5 mA ($p < 0.05$) for ischemic conditions. After 2 hours, m-RVR threshold had decreased an average of 21.1 ± 25.4 mA ($p < 0.005$, n = 18 pair) for nonischemic and 14.5 ± 27.8 mA ($p < 0.05$) for ischemic conditions.

Ventricular activation times: Activation times, reflecting ventricular conduction between the left ventricular plunge electrode and the right septal electrode, averaged 63.3 ± 11.5 ms in the control study without ischemia and 64.1 ± 12.7 ms with ischemia (n = 38), an insignificant change. During repeated measurements over time in the saline control group, no change occurred. During incremental administration of beta-blocking drugs, a gradual small increase in activation time was observed. Comparing measurements for optimal doses of each drug with control measurements, this increase averaged 6.2 ± 8.9 ms ($p < 0.002$). Significant increases in activation time for individual drugs were also noted for labetolol (nonischemic and ischemic), propranolol (nonischemic), and timolol (ischemic conditions).

Ventricular refractory periods: During the control study, left ventricular effective refractory period averaged 194 ± 19 ms (n = 36) without ischemia and 199 ± 20 ms with ischemia (p = not significant). In the saline control group, small variable changes over time (usually increases) were not significant. During incremental dosing with beta-blocking drugs, gradual increases in refractory periods were noted. After optimal drug dosing, effective refractory period increased by 29 ± 17 ms (n = 27, $p < 0.001$) for nonischemic and by 20 ± 16 ms (n = 26, $p < 0.001$) for ischemic conditions. Significant increases were also noted in refractory periods by paired analysis for each drug. Similar increases in refractory period were induced by stellectomy alone (23 ms, n = 5), and the addition of timolol did not lead to a further change. Refractory period increases thus appear to reflect antisympathetic effects.[27]

Blood pressure responses: Initial mean blood pressures averaged 82 ± 32 mm Hg. With time, blood pressure in the control (saline) and beta-blocking drug treatment groups showed insignificant and similar declines of 3.0 and 3.4 mm Hg at the end of optimal dosing. Adequate hydration and constant rate pacing were thus effective in preventing a relative decrease in blood pressure in the treatment versus control group.

Discussion

Our study documents substantial antifibrillatory effects of intravenously titrated beta-adrenergic blocking agents in an open chest, anesthetized dog model. The 5 agents tested possess a variety of accessory characteristics, but in full beta-blocking doses each was effective in augmenting VF threshold, including thresholds during acute ischemia, an average of 6-fold. Although a precise relationship of VF threshold augmentation and beta-blockade was not determined in this study, a generally parallel order of potencies was shown (Table III). Repetitive ventricular response thresholds, viewed as another index of antifibrillatory

effect,[1,22,28] were augmented in parallel with VF thresholds. Dependence of VF threshold on cardiac sympathetic stimulation was suggested by results of bilateral stellate ganglionectomy. The resulting increase in fibrillation threshold after stellectomy confirms recent experimental observations of Schwartz and Stone[29] and earlier observations by Kliks et al.[14] That further augmentation in threshold followed timolol suggests additional effects which may include blockade of circulating cathecholamines and blockade of residual cardiac sympathetic innervention; nonbeta-blocking pharmacologic actions appear to be a less likely explanation.[25]

A consensus has not yet been reached as to whether the preventive action of certain beta-blocking drugs on clinical sudden death represents a class or individual drug effect. Currently, the Food and Drug Administration requires each beta-blocking drug to submit to individual testing before approval is considered for the indication of prophylaxis of cardiac death. Our observations provide insight about the effect of accessory properties on experimental VF threshold augmentation. If membrane stabilizing (class I antiarrhythmic) properties were important, propranolol should show a relative advantage in dose or maximal effect over timolol. This was not noted, and a relative dose advantage of timolol could in fact be argued. Higher dose propranolol ($\geq$1 mg/kg) did not increase VF threshold further. The cardioselectivity of metoprolol did not appear to afford an advantage (or significant disadvantage). Alpha-blockade may have certain antiarrhythmic potential based on some arrhythmia models. However, labetolol was the least active on a milligram per kilogram basis of the drugs tested. This could be predicted from its relatively weak beta-blocking potency.[30] Pindolol in lowest doses showed less activity than timolol, although both are rated as equivalent in beta-blocking potency.[24] In this regard, recent preliminary observations of others suggest an adverse effect of intrinsic sympathomimetic activity on VF.[31] If the apparent disadvantage we noted for pindolol versus timolol is real, then pindolol's partial agonist activity may provide a plausible explanation. However, in larger doses, excellent antifibrillatory effects of pindolol were noted in our study. Our data are thus consistent with a general "class" effect of the beta-adrenoceptor blocking drugs on VF threshold. This effect presumably relates primarily to blocking effects on the cardiac beta-1 adrenergic receptors, an action that each of these drugs holds in common.

Beta-blocking drug administration also caused small increases in ventricular activation times and effective refractory periods in our model. Refractory period increases were also produced by stellectomy, suggesting antisympathetic effects to be the cause.[27] Ventricular impulse conduction velocity has recently been shown to have complex determinants, depending on depth (epicardial versus endocardial), direction (apical versus basal), and perfusion (ischemia) characteristics.[32] Regional discrepancies in conduction velocities may be more important than absolute velocities in determining propensity for experimental VF. Similarly, heterogeneity of ventricular refractoriness may be more important than average refractory period durations.[33] Beta-blocking drugs may act to "homogenize" heterogeneous sympathetic stimulation to the heart as occurs during ischemia and neurogenic stress.[34,35]

We determined control VF threshold measurements similar to those of other studies which have used the stimulus-train technique; average VF thresholds by this technique have ranged from 5 to 15 mA without ischemia and about 40% less (2 to 10 mA) during ischemia.[14,22,26,36,37] In contrast, methods using single or multiple extrastimuli to induce VF require similar currents during ischemia but higher currents in the absence of ischemia.[1,21,38] In our model, drug augmentation in VF threshold was a consistent and reproducible finding under both conditions.

Application of our experimental findings to the clinical setting must be made with caution. Experimental VF threshold is only 1 of many variables used to define an antiarrhythmic drug's potential for activity on the complex determinants of clinical VF.[39] Open-chest, anesthetized dogs represent a model with high sympathetic stimulation in which beta-blocking drugs may be particularly effective. Effects of various beta-blocking drugs in other models relevant to sudden cardiac death will thus be of interest.[39] However, other drugs that possess clinical antifibrillatory activity (lidocaine, bretylium) also elevate experimental VF threshold.[22,36,40] Elevation in VF threshold should thus be considered a potentially important protective mechanism by which beta-blocking drugs may reduce sudden cardiac death, particularly in the setting of ischemic heart disease. During performance of these studies, protective effects against sudden cardiac death of 3 of the agents tested—timolol, metoprolol, and propranolol—were reported in large scale, carefully designed studies.[11–13]

Recent observations with several antiarrhythmic agents suggest a lack of close correlation between antiectopic and antifibrillatory effects.[41–45] Bretylium, for example, is an excellent antifibrillatory drug but a poor antiectopic agent.[40,42,43] Similarly, lidocaine may exert antifibrillatory effects in instances in which antiectopic and antitachycardic actions are ineffective.[44,45] A model suggesting an explanation for lidocaine's action in this instance was recently presented[45]; microreentrant conditions necessary for VF may be prevented in situations in which macroreentry (ventricular tachycardia) or automatic or nonsustained reentrant ectopy is not.

Primary antifibrillatory action has been associated most strongly with a separate class (class III) of antiarrhythmic agents.[46,47] A member of this class, amiodarone, has also recently been postulated to be of positive benefit in preventing recurrent VF.[48] Induction of ventricular tachycardia by programmed ventricular stimulation can occur with either amiodarone or bretylium at a time when clinical control of recurring episodes of VF is manifest,[49,50] again drawing a distinction between effects on microreentrant VF and macroreentrant ventricular tachycardia or ectopic mechanisms.

In the past, inadequate studies have been performed to assess the antifibrillatory role of beta-blocking drugs, although individual studies have suggested experi-

mental antifibrillatory benefit for certain beta-blocking drugs.[21,23] However, the results of our study suggest that beta-blocking drugs as a group may possess antifibrillatory action which is of similar magnitude for optimal doses of each agent. The major effect of beta-adrenergic blocking drugs in increasing VF threshold in our experimental model appears to be best explained by blockade of cardiac beta-adrenergic impulses.

Acknowledgment: We thank Benedict R. Lucchesi, PhD, MD, K. C. Millar, MD, and J. A. Abildskov, MD, for helpful direction and suggestions. We are grateful to Heidi Vorn-Zandt, BS, Nancy Collier, BS, Roland F. Wyatt, MPH, and Bruce W. Steadman, BS, for technical assistance; and Keith D. Green, AS, for help in preparing the manuscript.

Effects of Exercise and Isoproterenol During Atrial Fibrillation In Patients With Wolff-Parkinson-White Syndrome

LAWRENCE D. GERMAN, MD, JOHN J. GALLAGHER, MD,
ARCHER BROUGHTON, MB, BS, TOM GUARNIERI, MD, and JOEY L. TRANTHAM, MD

The effects of exercise and isoproterenol on atrial fibrillation (AF) were studied in 17 patients with Wolff-Parkinson-White syndrome (WPW) to assess the risk of developing a rapid ventricular response. Mean cycle length (R-R interval) and shortest R-R interval between both preexcited and nonpreexcited QRS complexes were recorded, as well as the percentage of preexcited complexes during control periods, during bicycle exercise, and during isoproterenol infusion. Exercise resulted in significantly shorter mean cycle length and the shortest R-R interval between nonpreexcited complexes. Exercise also resulted in a significantly lower percentage of preexcited complexes during AF, but had no effect on the R-R intervals between preexcited complexes. Isoproterenol had a variable effect on the percentage of preexcited QRS complexes, but resulted in significant shortening of mean cycle length and the shortest R-R interval between both normal and preexcited complexes. With isoproterenol, 12 of 17 patients had shortest preexcited R-R intervals $\leq$215 ms, compared with 6 of 17 in the control state. Isoproterenol infusion increased the rate of conduction over the accessory pathway during AF and allowed better assessment of the risk of excessively rapid rates occurring during AF. Exercise is not an adequate test for this purpose.

The ventricular response to atrial fibrillation (AF) is of major importance in planning the treatment of patients with Wolff-Parkinson-White syndrome (WPW). In these patients, the functional properties of the accessory pathway determine whether or not excessively rapid ventricular rates are achieved during AF. It has been shown that patients with R-R intervals approaching 200 ms during AF are at risk for the development of ventricular fibrillation.[1,2] A single observation of the ventricular response during AF at rest may be insufficient to fully evaluate the risk faced by a patient with WPW. Changes in autonomic tone occurring during exercise or associated with anxiety or hypotension at the onset of the arrhythmia may influence the functional properties of accessory pathways and significantly affect the ventricular response during AF. To fully assess the potential for the development of life-threatening arrhythmias in patients with WPW, we studied the effects of an isoproterenol infusion and of bicycle exercise during AF. The results of these investigations in 17 patients with WPW are the subject of this report.

Methods

Patient population: These investigations were carried out as part of the routine electrophysiologic evaluation of patients referred to Duke University Medical Center with symptomatic arrhythmias due to the presence of accessory atrioventricular pathways. All patients were studied in the postabsorptive state after giving informed consent. Small doses of diazepam were occasionally given for sedation.

Seventeen patients are included in this group. All patients had anterogradely functioning accessory pathways located in the left free wall (8 patients), posteroseptal (6 patients), right free wall (2 patients), and antero-septal (1 patient) positions. Only 1 patient failed to demonstrate retrograde function of the accessory pathway.

Bicycle exercise was not performed in 3 patients. Patients were excluded from the study if AF in the control state was associated with an extremely rapid ventricular response causing hemodynamic compromise and requiring cardioversion to terminate the arrhythmia.

Isoproterenol infusion: Atrial fibrillation was induced by rapid atrial pacing through a coronary sinus catheter introduced from the left subclavian vein. All patients were studied without receiving cardiac arrhythmic drugs. A control period of AF was followed by continuous infusion of isoproterenol beginning at an infusion rate of 0.5 μg/min and increasing to 1, 2, 3, and 4 μg/min. The infusion rate was increased every 5 minutes until a rate of 4 μg/min was reached, or until symptoms associated with isoproterenol infusion became intolerable. Blood pressure was monitored frequently. No patient required discontinuation of isoproterenol infusion because of a change in blood pressure or the occurrence of chest pain. At peak isoproterenol infusion, AF was reinduced if sinus rhythm had supervened after the control period.

Exercise was not performed in 3 patients.
* $p > 0.1$.
† $p = 0.008$.
‡ Two consecutive preexcited complexes not seen.

Exercise: After discontinuance of the isoproterenol infusion, no further recordings were made for at least 20 minutes or until baseline sinus cycle length had returned if sinus rhythm supervened. Atrial fibrillation was reinduced for a preexercise control observation and exercise was then begun with the patient in the supine position with a bicycle ergometer at a load of 25 to 50 W and gradually increased to a maximum of 100 W as determined by the patient's physical condition. Exercise was performed to a minimum of 500 W-min and continued until terminated by patient fatigue. Atrial fibrillation was reinduced at peak exercise if sinus rhythm had supervened.

Surface leads I, II, III, V_1, and V_6 were recorded along with the intracavitary atrial electrograms on a Siemans-Elema Mingograf recorder at paper speed of 200 mm/s.

Atrial fibrillation was defined as rapid, disorganized atrial activity with multimorphic atrial electrograms recorded from the right atrium, the coronary sinus, or both, and an irregular ventricular response. The QRS complexes were classified as preexcited only if maximally anomalous QRS morphology was present. The mean R-R interval, shortest R-R interval between preexcited complexes, shortest R-R interval between nonpreexcited complexes, and the percentage of preexcited complexes during a minimum of 1 minute of AF were recorded for each intervention and compared with values obtained for the control period in each patient. The statistical analysis of these paired observations using each patient as his or her own control was performed using the Wilcoxon ranked sum test.

Results

Paired observations of mean R-R interval, shortest R-R interval between preexcited and also between non-preexcited complexes, and the percentage of preexcited complexes were made for each patient before and during isoproterenol infusion and exercise. The shortest R-R intervals between preexcited complexes in the control state and with isoproterenol and exercise are listed in Tables I and II, along with the percentage of preexcited QRS complexes for each intervention.

Effects of isoproterenol: Isoproterenol resulted in a significant shortening of the mean cycle length during AF ($p < 0.01$) (Fig. 1). During the control period, no patient had a mean R-R interval approaching 200 ms. With isoproterenol, 1 patient achieved a mean R-R interval of 195 ms. This patient (Patient 8) was 1 of the 2 patients who had had spontaneous ventricular fibrillation during AF. The other patient (Patient 4) with a history of ventricular fibrillation had a decrease in mean R-R interval from 327 to 248 ms.

Six patients had shortest preexcited R-R intervals of ≤215 msec in the control state, as opposed to 12 patients with isoproterenol, including both patients with histories of spontaneous ventricular fibrillation and 2 others with documented rates >300 beats/min during spontaneous AF before referral (Patients 5 and 7).

One patient (Patient 13) had only 9% preexcited complexes in the control state without any evidence of rapid conduction over the accessory pathway, and yet with isoproterenol preexcited 45% of complexes achieving a shortest R-R interval of 172 ms.

Isoproterenol resulted in a significant shortening of the shortest R-R interval between nonpreexcited complexes ($p < 0.01$). Two patients had R-R intervals of ≤205 ms between nonpreexcited complexes during isoproterenol. Neither patient had a history of ventricular fibrillation. There was no consistent effect of isoproterenol on the percentage of QRS complexes during AF that were preexcited.

Atrial fibrillation terminated spontaneously during isoproterenol infusion in 11 patients and shortly after termination of the infusion in 3. Atrial fibrillation reverted spontaneously to atrial flutter in 1 patient and reciprocating tachycardia in another. In 1 patient, AF persisted beyond the infusion and recovery period.

Effects of exercise: As with isoproterenol, exercise resulted in a significant shortening of the mean R-R interval during AF ($p < 0.01$). The shortening of mean R-R interval seen for the entire group was similar with exercise and isoproterenol (72 and 72 ms, respectively). Patient 8, who had had spontaneous ventricular fibrillation during an episode of AF, achieved a mean R-R

interval of 196 ms during exercise (234 ms during control). This patient had also demonstrated similar shortening of mean R-R interval with isoproterenol (195 ms). This patient's QRS complexes were all maximally preexcited during AF in the control, exercise, and isoproterenol periods.

There was no significant change in the shortest R-R interval between preexcited QRS complexes with exercise. Four patients had shortest preexcited R-R intervals of ≤205 ms with exercise, including both patients with histories of spontaneous ventricular fibrillation; however, all 4 patients had shortest preexcited R-R intervals of ≤227 ms (3 under 200 ms) in the control period.

Exercise caused a significant shortening of R-R intervals between non-preexcited complexes ($p < 0.01$). The shortest nonpreexcited R-R interval seen was 215 ms, occurring in a patient with no history of rapid ventricular response to AF.

In contrast to isoproterenol, exercise caused a significant decrease in the percentage of preexcited QRS complexes ($p < 0.01$), with a change in the group means from 70% preexcited complexes in the control state to 41% with exercise. The change in percentage of preexcited complexes was variable among patients, however, with 3 patients increasing the percentage of preexcited QRS complexes by only 3, 8, and 2%, respectively. Atrial fibrillation reverted spontaneously during exercise in 11 patients and shortly after exercise termination in 3 patients.

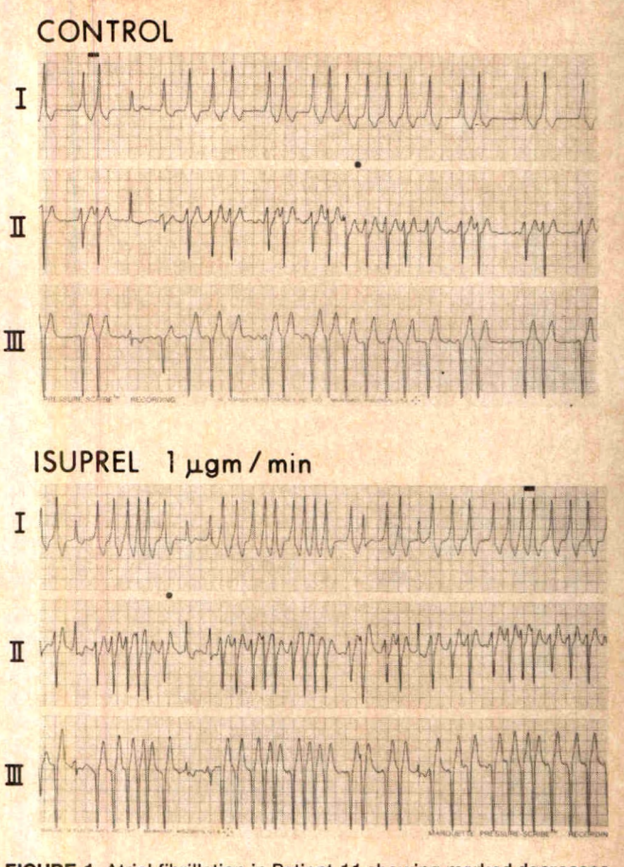

FIGURE 1. Atrial fibrillation in Patient 11 showing marked decreases in mean cycle length (R-R interval) and shortest interval between preexcited complexes during isoproterenol infusion. Nonpreexcited complexes are present before and during isoproterenol.

Discussion

The possibility of the development of a rapid ventricular response to spontaneous AF is of major concern in advising patients with WPW. The natural history of arrhythmias in these patients is sufficiently variable to preclude a confident assessment of this risk even in patients who have not previously demonstrated spontaneous AF. A previous study[3] demonstrated the ineffectiveness of exercise testing in inducing spontaneous arrhythmias in these patients, and the normalization of the preexcited QRS complex with exercise is also well known. This finding may represent rate-related block in the accessory pathway in some patients but more commonly is due to the vagolytic effect of exercise in enhancing atrioventricular nodal conduction. For this reason, exercise would not be expected to provide a reliable test of the risk an individual with WPW faces for rapid ventricular rates during AF. A large reduction in preexcited QRS complexes with exercise does not exclude a rapid ventricular response with isoproterenol. In our study, 10 patients had a reduction with exercise in the percentage of preexcited QRS complexes during AF. Of these 10, five reduced the percentage of preexcited complexes dramatically, with 2 becoming totally nonpreexcited, 2 going from 100% preexcited to 10% and 18%, and 1 going from 78 to 3%. With isoproterenol, however, these patients had preexcited QRS complexes showing shortest R-R intervals of 180, 160, 200, 252, and 235 ms.

The variability of changes in preexcitation in response to exercise may reflect a variety of factors, including the baseline state of autonomic tone, the relation between the refractory periods of the accessory pathway and the atrioventricular node, and the location of the pathway. The balance between vagolytic and sympathetic effects during exercise and the degree of physical training of the individual may also play a role.

Enhanced atrioventricular nodal conduction during exercise may permit retrograde concealed conduction into the accessory pathway. This would result in the failure of anterograde conduction down the accessory pathway, and thereby produce normalization of the QRS complex without any direct effect on accessory pathway refractoriness.

Because of the small number of right-sided and anteroseptal pathways in this group, we cannot make any conclusions regarding the effect of pathway location on R-R intervals during AF.

Isoproterenol produces a shortening of atrioventricular nodal refractoriness and enhances atrioventricular nodal conduction.[4] Wellens et al[5] reported a correlation between accessory pathway refractoriness and ventricular rate during AF, and recently reported shortening of the anterograde refractory period of accessory pathways with isoproterenol.[6] We observed both a shorter mean cycle length and shorter R-R intervals

between preexcited complexes with isoproterenol. Although there was no consistent effect on the percentage of preexcited complexes during AF, 1 patient dramatically increased the percentage of preexcited complexes with isoproterenol. The shortest R-R interval between non-preexcited complexes was also significantly shortened suggesting a uniform effect of isoproterenol on enhancing conduction down both the atrioventricular node and accessory pathway.

Our study confirms previous observations[3] that exercise frequently results in a less preexcited QRS in patients with WPW and demonstrates that this holds true during AF as well. This limits the usefulness of exercise as a means of assessing the risk of a rapid ventricular response in patients with WPW. Although many patients who display very short (≤200 ms) R-R intervals between preexcited complexes during AF with isoproterenol also have relatively short R-R intervals in the control period (≤230 ms), some patients may have few or no preexcited complexes during AF and yet with isoproterenol may preexcite a significant number of complexes and achieve very short R-R intervals. The absence of rapid preexcited ventricular rates during AF in the presence of isoproterenol probably implies a low risk for the spontaneous occurrence of ventricular fibrillation. The usefulness of esophageal pacing as a noninvasive means of inducing AF in the evaluation of these patients has recently been reported.[7]

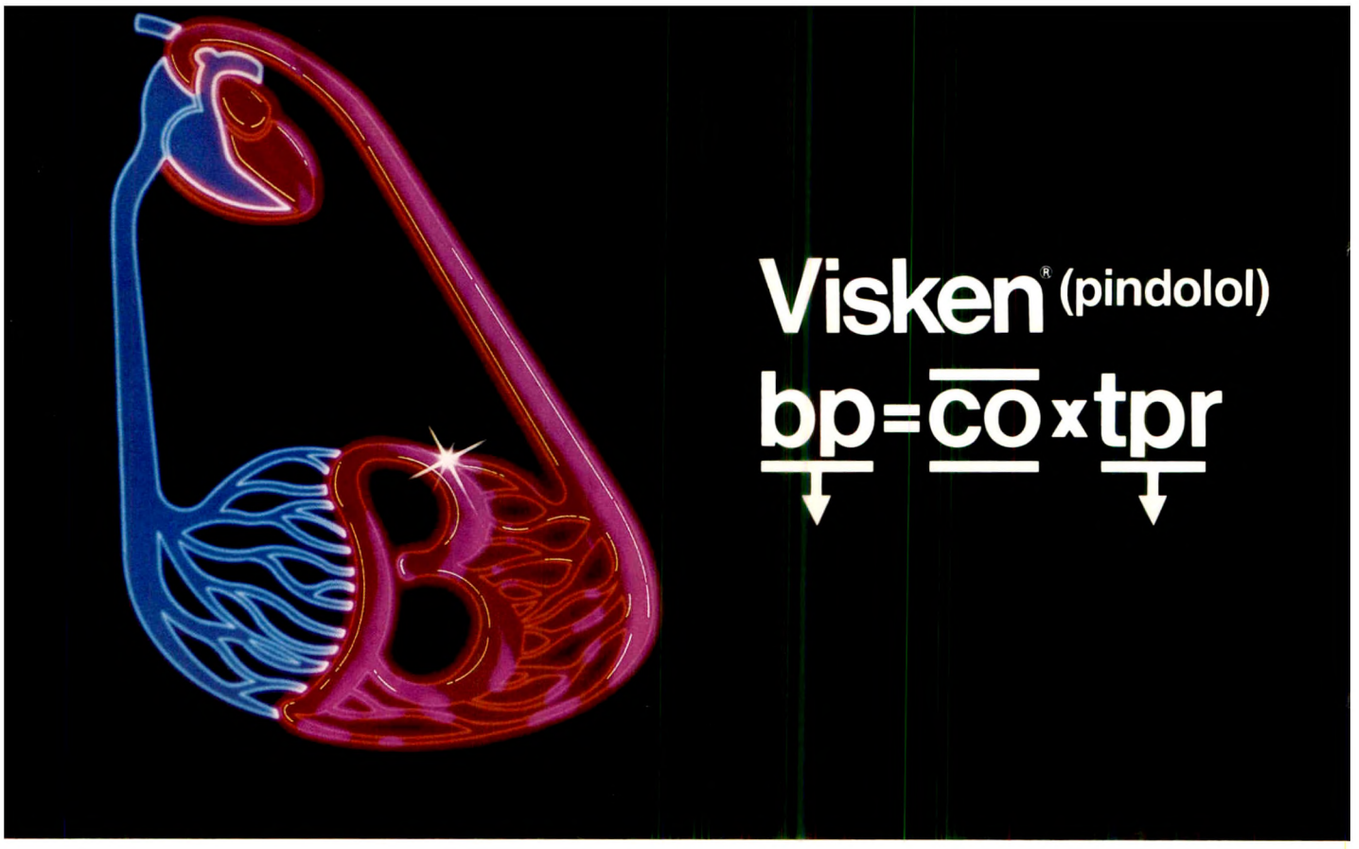
The Visken® (pindolol) difference
All other beta blockers
bp = co x tpr
Visken (pindolol)
bp = co x tpr



Makes hemodynamic sense in the treatment of hypertension

Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

Reduces total peripheral resistance*

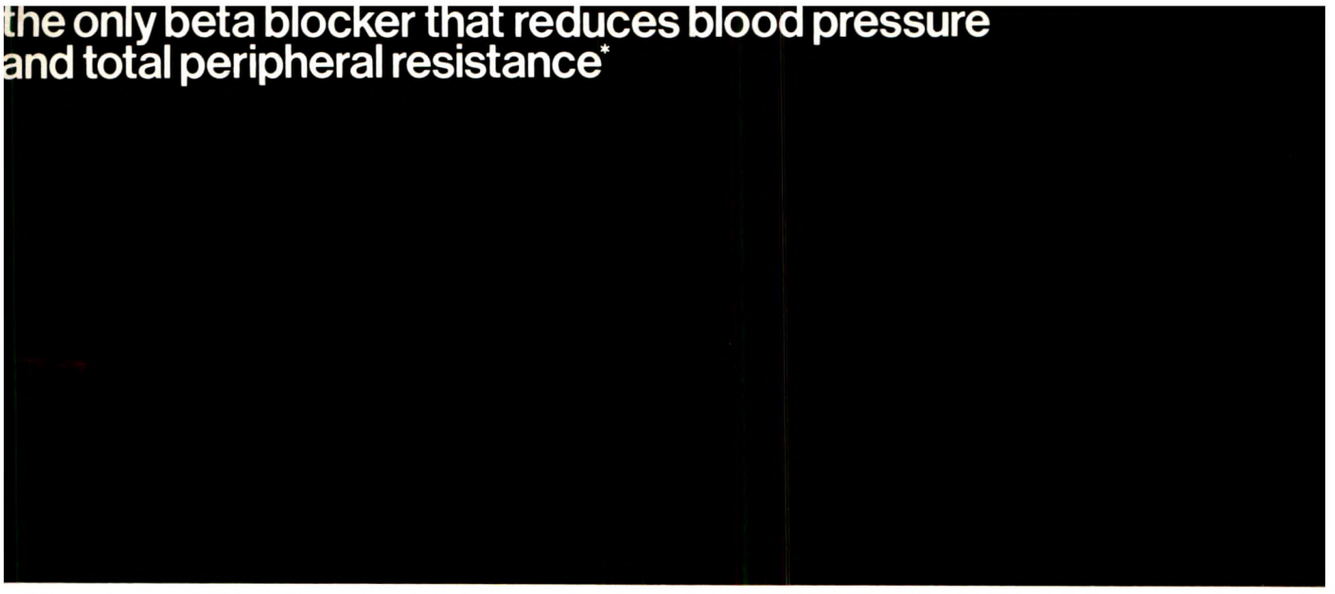
Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

© 1983 Sandoz, Inc.

*The clinical significance has not been evaluated. See clinical significance statement on facing page of this advertisement.



Has little effect on resting heart rate

Visken® (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute.

The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

Maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

Favorable side effect profile

Low incidence of bradycardia

Low incidence of cold extremities

Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

*See clinical significance statement.

Please see next page of this advertisement for brief summary of prescribing information.

Visken® (pindolol)

Available in 5 mg and 10 mg tablets

Convenient bid dosage

Dosage should be titrated on an individual basis.
Many patients respond to 10-30 mg a day in divided doses.

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE
Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS
Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS
Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS
Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY
Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS
Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elici Visken (pindolol) (N = 322) %	Active Controls* (N = 188) %

*Active Controls: Patients received either propranolol, ∝-methyldopa diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse re were seen in 2% or fewer patients and their relationship Visken (pindolol) is uncertain. AUTONOMIC NERVOUS TEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, cation, cold extremities, heart block, hypotension, sync tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RATORY: wheezing; UROGENITAL: impotence, pollakiu MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS
In addition, other adverse effects not listed above have b ported with other beta-adrenergic blocking agents and s be considered potential adverse effects of Visken (pindol

Central Nervous System: Reversible mental depression gressing to catatonia; an acute reversible syndrome cha ized by disorientation for time and place, short-term me loss, emotional lability, slightly clouded sensorium, and creased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with achin sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and n thrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis; ischem colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the blocker practolol has not been reported with Visken (pin during investigational use and extensive foreign experien amounting to over 4 million patient-years.

OVERDOSAGE
No specific information on emergency treatment of overd is available. Therefore, on the basis of the pharmacologi tions of Visken (pindolol), the following general measure should be employed as appropriate in addition to gastric

Excessive Bradycardia: administer atropine; if there is n sponse to vagal blockade, administer isoproterenol cauti

Cardiac Failure: digitalize the patient and/or administer uretic. It has been reported that glucagon may be useful situation.

Hypotension: administer vasopressors, e.g., epinephrin levarterenol, with serial monitoring of blood pressure. (T evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent suc isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an of 500 mg of Visken (pindolol) by a hypertensive patient. pressure increased and heart rate was ⩾80 beat/min. Re was uneventful. In another case 250 mg of Visken (pindo was taken with 150 mg diazepam and 50 mg nitrazepam, ducing coma and hypotension. The patient recovered in 2 hours.

DOSAGE AND ADMINISTRATION
The dosage of Visken (pindolol) should be individualized. recommended initial dose of Visken (pindolol) is 10 mg b. alone or in combination with other antihypertensive agent Many patients will respond to 15 mg per day (5 mg t.i.d.) antihypertensive response usually occurs within the first of treatment. If a satisfactory reduction in blood pressure not occur within 2-3 weeks, the dose may be adjusted in ments of 10 mg per day at 2-3 week intervals up to a ma of 60 mg per day.

HOW SUPPLIED
White, round, scored tablets: 5 mg and 10 mg, packages 100. 5 mg tablets embossed "VISKEN 5" on one side, an "78-111" and scored on other side (NDC 0078-0111-05). tablets embossed "VISKEN 10" on one side, and "78-73" scored on other side (NDC 0078-0073-05). [VIS-Z2 9

VIS-3

Prevalence and Correlates of Posterior Extra Echocardiographic Spaces in a Free-Living Population Based Sample (The Framingham Study)

DANIEL D. SAVAGE, MD, PhD, ROBERT J. GARRISON, MS, FREDERICK BRAND, MD, MPH, SANDRA J. ANDERSON, BS, RN, WILLIAM P. CASTELLI, MD, WILLIAM B. KANNEL, MD, MPH, and MANNING FEINLEIB, MD, DrPH

To obtain epidemiologic information on extra echocardiographic spaces immediately posterior to the left ventricular free wall, 2,028 subjects in the original Framingham cohort study (mean age 70 ± 7 years) and 3,624 of the offspring of the cohort (and their spouses) (mean age 44 ± 10 years) with adequate echocardiograms were evaluated. Extra echocardiographic spaces were detected in 370 (6.5%) of the 5,652 subjects. The prevalence ranged from <1% in subjects in the 20- to 30-year age decade to >15% for those in their 80s. Extra echocardiographic spaces tended to be more common in subjects who were older, female, obese, more hypertensive, and who had higher blood sugar levels and higher low density lipoprotein cholesterol levels (measured 8 years earlier). The high prevalence of extra echocardiographic spaces and the independent association with age (cohort and offspring), obesity (cohort and male offspring), and ventricular septal hypertrophy (cohort and male offspring) is compatible with at least 2 hypotheses among others that should be tested: (1) Subepicardial fat may often masquerade as pericardial fluid producing a posterior extra echocardiographic space, especially in obese elderly subjects. (2) Small posterior extra echocardiographic spaces may often be early markers of subclinical hypertensive heart disease.

One of the earliest clinical uses of echocardiography was the diagnosis of pericardial effusion. Echocardiography is now considered the safest, most expedient, and most reliable method for making this diagnosis.[1,2] In the past, extra echocardiographic spaces found anterior to the right ventricular free wall in the absence of such spaces posteriorly were thought to represent fat, whereas posterior extra echocardiographic spaces were usually thought to be pericardial fluid.[2,3] Such effusions could be physiologic (in small amounts) or pathologic.[4] Clinical reports differ regarding the significance of these effusions and their prevalence. Prevalence estimates from these reports range from 5 to 49%.[5–18] Clinical studies have indicated that these echo-poor spaces are frequently associated with various cardiac disorders, including congestive heart failure, pericarditis, myocardial infarction, and hypertensive heart disease among others.[4,19,20] Such echo-poor spaces are also frequently found unexpectedly in patients without overt cardiac disease.[4,19]

Population-based data are lacking regarding these echo-poor spaces. Such data can give prevalence estimates that are less affected by selective bias and might yield clues regarding the pathogenesis of such echo-poor spaces. To this end, echocardiographic studies being conducted in the ongoing prospective population-based Framingham Study were used to assess the prevalence and correlates of extra echocardiographic spaces.

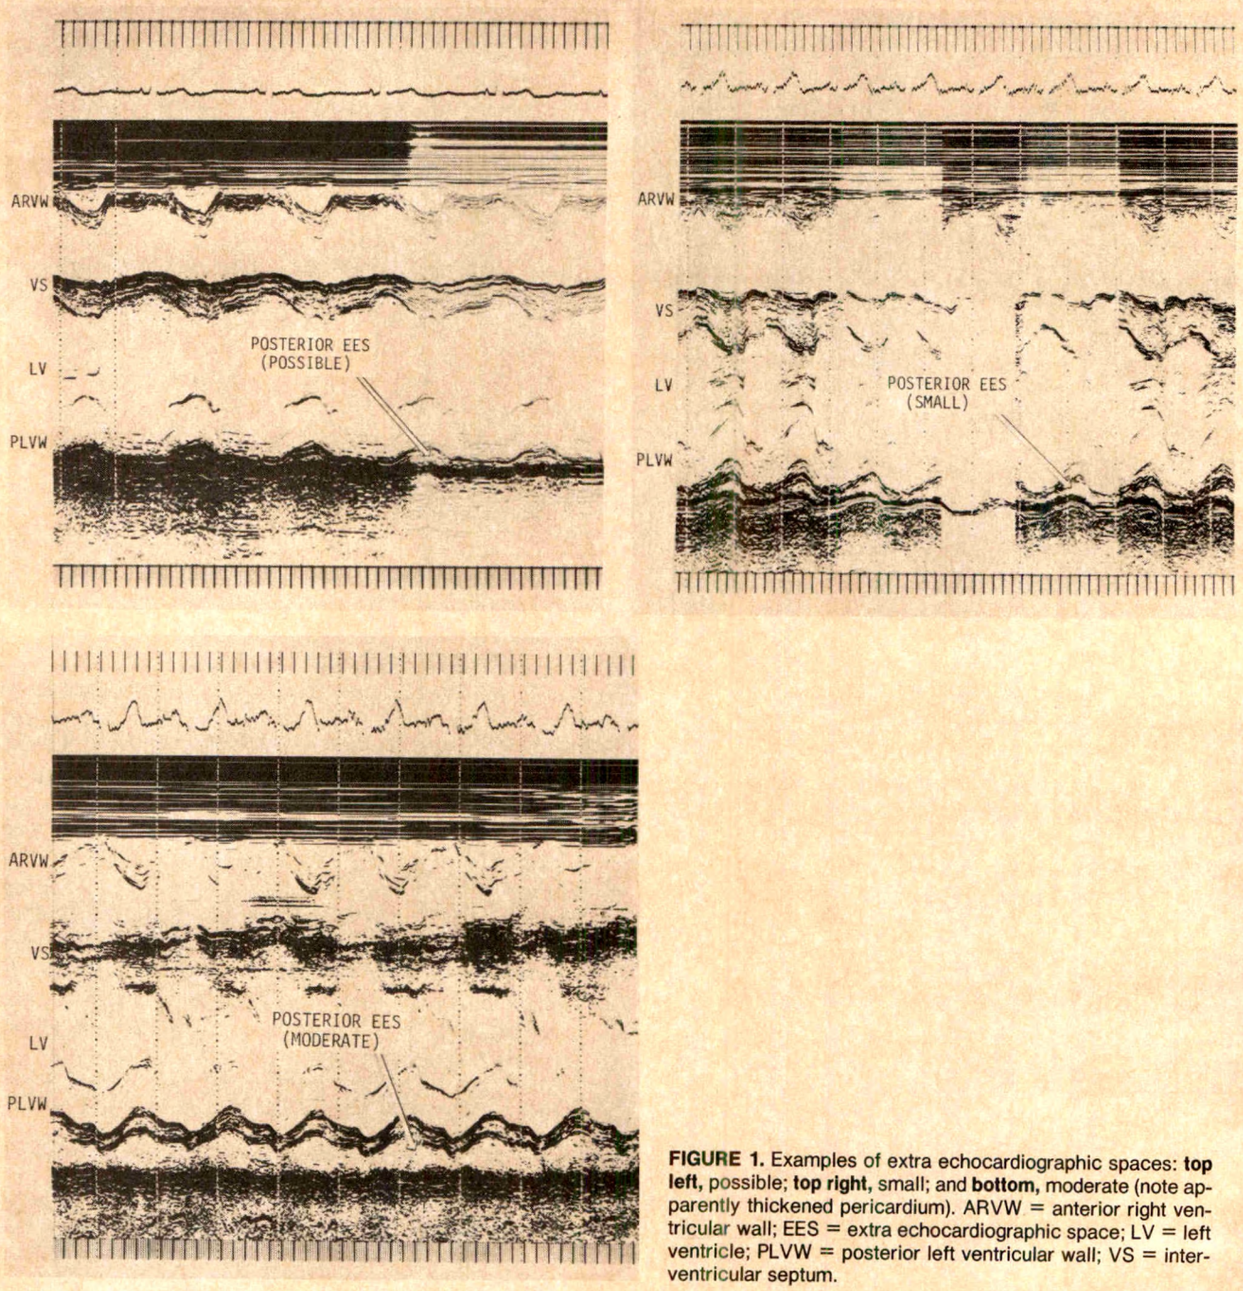

FIGURE 1. Examples of extra echocardiographic spaces: **top left,** possible; **top right,** small; and **bottom,** moderate (note apparently thickened pericardium). ARVW = anterior right ventricular wall; EES = extra echocardiographic space; LV = left ventricle; PLVW = posterior left ventricular wall; VS = interventricular septum.

Methods

Subjects: At the time of this report, 2,287 of the original Framingham cohort (biennial examination 16) and 3,664 offspring (examination 2) of the original cohort (and their spouses) had been studied by M-mode echocardiography. All subjects gave informed consent before the study. Detailed accounts of the sampling procedure for these populations and the clinical methods employed have been reported elsewhere.[21,22] Echocardiograms of adequate quality to assess the area immediately posterior to the left ventricular free wall were obtained in 1,230 female and 798 male subjects in the cohort group (mean age 70 ± 7 years [standard deviation], range 59 to 90). Interpretable echocardiograms were found in 1,871 female and 1,753 male patients in the offspring study group (mean age 44 ± 10 years, range 17 to 77). Quetelet's index (weight in kilograms divided by height in meters raised to the second power) was used as a measure of obesity. Evidence of overt cardiac disease was considered present if there were Framingham criteria for coronary disease, congestive heart failure, hypertensive heart disease, valvular heart disease (such as rheumatic heart disease), or miscellaneous "other" heart diseases (such as cardiomyopathy).[23] Clinical information obtained at the time of echocardiography was used for these diagnoses.

Echocardiographic methods: M-mode echocardiography was performed in the partial left lateral decubitus position with the head of the bed elevated 30°. Standard techniques were employed with the transducer preferentially in the fourth intercostal space parasternally.[24] Care was taken to avoid false-positive recordings secondary to aiming the transducer too medially.[5] Automatic gain control and variable damping

were used to aid in identification of echo-poor spaces posterior to the left ventricular free wall. Spatial orientation was aided by the use of 2-dimensional echocardiography in more than 90% of studies which helped to distinguish the descending aorta from other causes of posterior extra echocardiographic spaces. Two-dimensional echocardiography also aided in placing the cursor for the M-mode echocardiogram to assess the maximal extent of the extra echocardiographic space for semiquantitative classification (see later).

Recordings were made using an Aerotech 2.25 MHz focused transducer, a Hoffrel 201 echocardiograph interfaced with a Honeywell 1856 line scan recorder, and a Jason thermographic printer. A Hoffrel mechanical sector scanner was used for 2-dimensional echocardiograms. Only posterior extra echocardiographic spaces were considered in the present report, because of the poorer resolution of anterior versus posterior structures with the equipment used. The criterion used for a posterior extra echocardiographic space was an echo-poor space immediately behind the posterior left ventricular wall which persisted throughout the cardiac cycle. When such spaces were present throughout only some of the cardiac cycles (and only during systole in other cardiac cycles), the spaces were considered "possible." If a posterior extra echocardiographic space measured ≥10 mm in depth, it was considered moderate in size. Between these extremes, the spaces were defined as small (Fig. 1). Left ventricular wall thickness, left ventricular internal dimensions, and left atrial dimension were measured using previously described echocardiographic methods.[25] Such measures were considered abnormal if they were greater than published 95% confidence limits adjusted for age and body size.[25]

Statistical analyses: Where appropriate, Student's *t* test, the chi-square test, or Fisher's exact test was used to assess statistical significance. To assess the relation of the echo-poor spaces to known risk factors for cardiac disease, univariate and multivariate logistic regression analyses were used. Regression analyses were performed using the maximal likelihood estimation and testing procedure described by Walker and Duncan.[26] Each estimated regression coefficient was tested against the alternate hypothesis that a particular partial coefficient was zero. A test outcome indicates whether the independent variable in question makes a statistically significant contribution to the prediction of an extra echocardiographic space.

The dependent variable used in multivariate analyses was the presence of a posterior extra echocardiographic space, whereas the independent variables were age, sex, Quetelet's index, systolic blood pressure, blood sugar, cigarette use, and serum high and low density lipoprotein cholesterol. In contrast to the current examination data used to assess clinical diagnoses (see earlier), the cardiovascular risk factors used as independent variables (except current age) were measured 8 years before echocardiography was performed.

Results

Posterior extra echocardiographic spaces were found in 370 (6.5%) of the 5,652 subjects. The prevalence

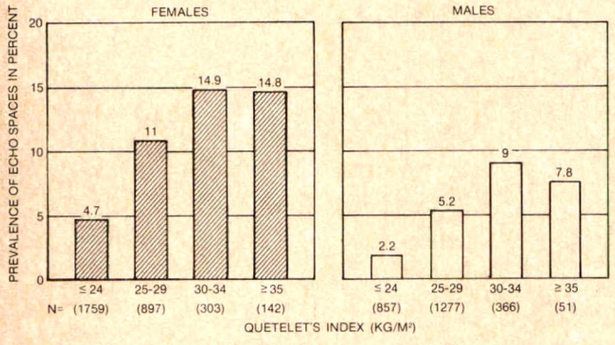

FIGURE 3. Relation of posterior extra echocardiographic spaces to Quetelet's index in Framingham subjects.

ranged from <1% in subjects in the 20- to 30-year age decade to more than 15% for those in their 80s. Figure 2 summarizes the prevalence of these spaces in Framingham Study subjects. The extra echocardiographic spaces were categorized as possible in 198 (56%) of the 370 subjects with such spaces. Only 18 of the subjects (9 male, 9 female; mean age 68 ± 12 years) had extra echocardiographic spaces of moderate size. Only 30 (1.2%) of 2,411 subjects under age 50 years had extra echocardiographic spaces. The spaces in subjects under age 50 were invariably <10 mm.

With some exceptions, extra echocardiographic spaces tended to be more common in subjects who were older, female, obese, and more hypertensive and who had higher blood sugar and higher low density lipoprotein cholesterol levels (Tables I and II). Among these cardiovascular risk factors, obesity and age were significantly and independently associated with such echocardiographic spaces in multivariate analysis (Fig. 2 and 3, Tables III and IV). In Offspring Study female subjects, only age was significantly and independently associated with extra echocardiographic spaces (Table IV). High density lipoprotein cholesterol was significantly and independently associated with the echocardiographically poor spaces in elderly men. No overt cardiac disease was found in 241 (65%) of the 370 subjects with extra echocardiographic spaces. Overt cardiac disease was no more common in those with than in those without possible or small extra echocardiographic spaces in age- and sex-specific comparisons. Thirteen (72%) of the 18 subjects with moderate-sized spaces had overt cardiac disease. This figure was nearly twice the prevalence of overt cardiac disease found in those of similar age and sex without extra echocardiographic spaces. A variety of cardiac diseases were found in the 13 subjects, including hypertensive heart disease (7), valvular heart disease (3), coronary heart disease (2), and hypertrophic cardiomyopathy (1). Two subjects with hypertensive heart disease also had symptoms suggesting congestive failure. One subject with moderate effusion had an apparently thickened pericardium (Fig. 1, bottom), but no significant symptoms.

Hypertrophy of the interventricular septum or increased left ventricular mass was the only echocardiographic finding in cohort subjects that was consistently and significantly associated with such spaces in both sexes using age- and body size-adjusted comparisons. Interventricular septal hypertrophy was more than twice as likely in those with (32 of 194) than in those without (101 of 1,370) extra echocardiographic spaces ($p < 0.0001$). Echocardiographic left ventricular hypertrophy was significantly more likely in male Offspring Study subjects with than without extra echocardiographic spaces. Atrial fibrillation was 3 times more likely in cohort subjects with (13 of 215) than without (44 of 1,828) extra echocardiographic spaces ($p < 0.02$).

Discussion

The present study indicates a striking increase in the prevalence of posterior extra echocardiographic spaces with increasing age. The variance in prevalence estimates of extra echocardiographic spaces from clinical studies is undoubtedly partially explained by age differences and selective bias in the study groups. Data from the present study indicate that posterior extra echocardiographic spaces are common after age 60, with prevalences reaching 10 to 20%, whereas they are uncommon (prevalence about 1%) in subjects under age

50. In this free-living general population these spaces were usually small, with only 18 (0.3%) of the study group having moderate-sized spaces.

Berger et al[4] found moderate (>10 mm) or large (>20 mm) spaces in almost half the 171 patients they studied with extra echocardiographic spaces. Of their subjects, 95% had overt cardiac or systemic disease. In another clinical series, Riba and Morganroth[19] found overt cardiac disease in 41 (60%) of 68 patients who had clinically unsuspected extra echocardiographic spaces. They found extra echocardiographic spaces frequently in the setting of congestive heart failure. Rare causes of extra echocardiographic spaces have included pericardial neoplasm, coronary artery aneurysm, fistula, posterior thoracic aorta, left ventricular pseudoaneurysm, mitral anular calcification, and pleural effusion.[27–30] Subjects in the present study with possible or small areas usually had no overt cardiac disease, whereas subjects with moderate-sized spaces usually had overt cardiac disease. Only 1 subject with moderate-sized spaces had overt congestive heart failure.

Anterior extra echocardiographic spaces in the absence of posterior spaces were usually considered to represent epicardial fat.[2,3] Recent computerized tomography correlations with echocardiography confirm this impression.[31] Computerized tomographic study of 50 patients who had posterior extra echocardiographic spaces disclosed subepicardial fat both anteriorly and posteriorly in 18 patients.[32] The posterior spaces had an echocardiographic appearance indistinguishable from that of pericardial fluid.

Obesity is associated with increased subepicardial fat. Although such fat is more common and found in greater amounts anteriorly, appreciable aggregations of fat may be found posterior to the left ventricular free wall. Autopsy data indicate that subepicardial fat increases with age.[33] The strong relation of obesity and increased age to the presence of posterior extra echocardiographic spaces in the present study is consistent with the hypothesis that many spaces represent subepicardial fat with or without small amounts of (perhaps physiologic) pericardial fluid. The lack of overt evidence of cardiac disease in most subjects in the present study gives additional support to this hypothesis.

Obesity, hypertension, and ventricular septal hypertrophy are related and suggest another mechanism favoring fluid as an explanation for extra echocardiographic spaces. Pericardial fluid could be a marker for subclinical congestive heart failure in hypertensive patients with ventricular hypertrophy. The relatively poor cardiovascular risk factor profile in subjects with extra echocardiographic spaces is compatible with this possibility. Hypertensive hypertrophy is also a prominent precursor to atrial fibrillation.[34] However, in the cohort, the correlation of echocardiographic spaces with obesity was more impressive than that with interventricular septal hypertrophy. Furthermore, when ventricular septal hypertrophy was included in the multivariate analysis the obesity-echocardiographic space relation persisted.

The association of atrial fibrillation with extra echocardiographic spaces in the present study is consistent with the known association of atrial dysrhythmias with pericardial disease. However, Isner et al[35] have described computerized tomographic evidence of accumulations of fat in the interatrial septae in obese patients. Whether this might be associated with extra echocardiographic spaces (secondary to subepicardial fat) and lead to atrial dysrhythmias deserves investigation. Whether the lack of a significant relation of extra echocardiographic spaces to obesity in the younger Offspring Study female subjects indicates a different pathogenesis compared with that in male and older subjects is unclear but also deserves investigation. The association of high density liproprotein cholesterol with extra echocardiographic spaces in elderly men is not easily explained.

In any event, recognition that posterior extra echocardiographic spaces may in some cases represent subepicardial fat is important because it could help

avoid labeling subjects with nonspecific symptoms as having pericarditis. The possibility of alternative explanations for such spaces deserves further study. Such study should include evaluation of the specificity of various echocardiographic findings as indicators of fluid. In the meantime, computerized tomography may be useful in confirming the presence of pericardial fluid. This is appropriate when fluid and fat must be distinguished (for example, contemplated pericardiocentesis) in the presence of any doubt about the echocardiographic findings.

Effect of Verapamil on Left Ventricular Function: A Randomized, Placebo-Controlled Study

RONALD E. VLIETSTRA, MB, ChB, MARIA A. C. FARIAS, PhD, ROBERT L. FRYE, MD, HUGH C. SMITH, MD, and ERIK L. RITMAN, MD, PhD

Verapamil has a negative inotropic action in isolated cardiac muscle. Its effects on left ventricular function were tested in 25 patients with suspected coronary artery disease. A double-blind, randomized, placebo-controlled study design was used. Verapamil (0.2 mg/kg over 10 minutes) significantly lowered mean arterial pressure (from 105 to 89 mm Hg) while increasing the cardiac index (from 2.8 to 3.1 liters/min/m^2). No statistically significant effect was seen on heart rate, left ventricular end-diastolic pressure or end-systolic volume index, ejection fraction, peak rates of systolic wall thickening or diastolic wall thinning, or percentage of hemiaxial shortening. However, there was a small increase in the left ventricular end-diastolic volume index (from 94 to 102 ml/m^2). Important findings were a reduction in systemic vascular resistance (from 39 to 30 U·m^2), an increase in left ventricular end-diastolic volume index consistent with a negative inotropic effect, and no evidence of improved regional wall dynamics in portions of the left ventricular wall considered hypokinetic because of myocardial ischemia.

The calcium channel-blocking drug verapamil has clinically important cardiovascular effects. Its slow-channel inhibition in vascular smooth muscle and myocardium produces systemic and coronary vasodilatation and depression of sinoatrial and atrioventricular nodal function.[1] Recognition of these properties has led to its successful use in chronic angina pectoris,[2,3] coronary artery spasm,[4,5] and supraventricular tachycardias.[6,7]

In vitro studies show, however, that verapamil depresses myocardial contractility.[8,9] Some impairment in myocardial function has also been noted in open-label patient studies performed in the cardiac laboratory.[10,11] Available evidence suggests that this in vivo effect is chiefly seen in patients who have markedly impaired ventricular function.

We thus sought to examine the effects of verapamil on global and regional left ventricular function in patients with suspected coronary artery disease but without evidence of heart failure. We wished to test for adverse effects of the drug on indexes of left ventricular function in such patients, and, in addition, to test the hypothesis that regional wall dynamics in areas of myocardium presumed to be ischemic improve after administration of verapamil.

Methods

Serial measurements of cardiac function made in the catheterization laboratory are known to be subject to many sources of variation.[12] To minimize the biases these and other variations would introduce, we used a randomized, double-blind, placebo-controlled study design.

Selection of patients: The patients selected had been referred to the cardiac laboratory for coronary arteriography because of suspected coronary artery disease, usually on the basis of the presence of angina pectoris. They had no evidence of other heart disease, and there were no clinical signs of heart failure. Study patients were not taking other cardioactive medications. Specifically, no beta-adrenergic blockers had been administered during the 48 hours before the study and no nitrates had been given within 12 hours. The investigation was approved by the Mayo Clinic Human Studies Committee. It was discussed with each patient, and informed consent was obtained.

Study protocol: The study was performed before coronary arteriography and utilized a fluid-filled catheter in the left ventricle and a cannula in the left brachial artery. Baseline measurements were obtained of arterial pressure, heart rate, left ventricular end-diastolic pressure, and cardiac output as determined from an indocyanine green dye curve, with in-

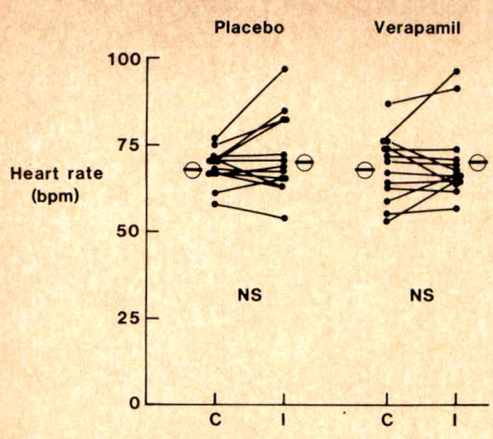

FIGURE 1. Control (C) and postintervention (I) values for heart rate in placebo and verapamil treatment groups. Differences are not significant (NS). The **larger circles** represent mean values. bpm = beats per minute.

TABLE I Effects of Verapamil on Left Ventricular Function: Results of Randomization (Mean Baseline Values)

Variable	Placebo (12 Patients)	Verapamil (13 Patients)*
Age (yr)	55	55
Vessels diseased (n)	2.1	2.0
Heart rate (beats/min)	68	68
Mean arterial pressure (mm Hg)	103	105
Cardiac index (liters/min/m^2)	2.9	2.8
Left ventricular end-diastolic pressure (mm Hg)	17	16
Left ventricular end-diastolic volume index (ml/m^2)	91	94
Left ventricular end-systolic volume index (ml/m^2)	37	39
Ejection fraction (%)	60	58

* Ventriculographic data available for only 9 patients.

jection of dye into the left ventricle and brachial artery sampling. A biplane left ventricular videoangiogram was obtained after injecting 0.5 ml/kg of Renografin®-76 over 3 seconds. After the patient had rested 5 minutes, a bolus intravenous injection of 0.1 mg/kg of verapamil or placebo was given. This was followed by a 10-minute infusion of 0.01 mg/kg/min, for a total dose of 0.2 mg/kg. At the end of the infusion, repeat measurements were made of arterial pressure, heart rate, left ventricular end-diastolic pressure, and cardiac index, and another left ventricular videoangiogram was obtained.

Analysis of ventriculograms: The left ventriculograms were analyzed by biplane roentgen videometry interfaced with a CDC 3500 computer, as previously described.[13,14] Bright outlines are automatically generated by a videoquantizer to identify the endocardial and epicardial borders for computer analysis. Ventricular volumes and ejection fraction are determined from the endocardial outlines with use of a volume-computing program based on Simpson's rule. Peak rates of regional myocardial thickening and thinning are computed from 60-per-second measurements of the ventricular wall thickness, defined as the shortest distance between the endocardium and the epicardium. In this study, the peak rates were determined from a single segment of the anterolateral wall, approximately midway between the apex and the base of the heart. The advantages and limitations of this method of assessing regional myocardial function have been discussed previously.[14,15]

Regional contraction was also assessed from measurements of hemiaxial shortening. The measurements were obtained by manually superimposing end-diastolic and end-systolic left ventricular silhouettes, the diaphragm and ribs being used as fixed reference points. The silhouettes were then rotated onto a common midaortic valve-to-apex axis, and 3 equidistant cords were drawn to yield 6 hemiaxes.[11]

Coronary arteriography was performed by standard techniques, and angled views were routinely obtained. The degree of coronary arterial narrowing was judged subjectively and was expressed as the mean percentage of reduction in luminal diameter of the coronary artery from multiple views. Routine 12-lead electrocardiograms and vectorcardiograms were reviewed for evidence of transmural myocardial infarction.

Statistical analysis: The randomization code was broken only after all patient studies and measurements had been completed. The significance of differences obtained between control and intervention values was tested by Student's paired *t* test.

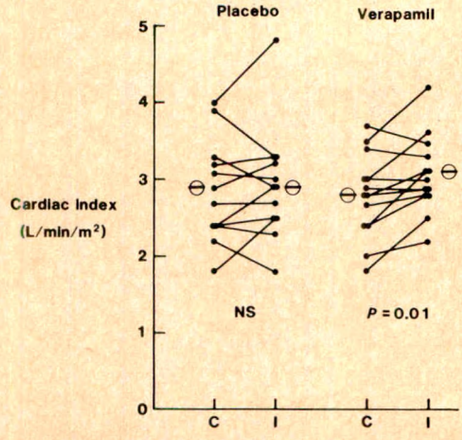

FIGURE 3. The values for cardiac index showed a small but significant increase ($p = 0.01$) when verapamil was the intervention. C = control; I = intervention; NS = not significant.

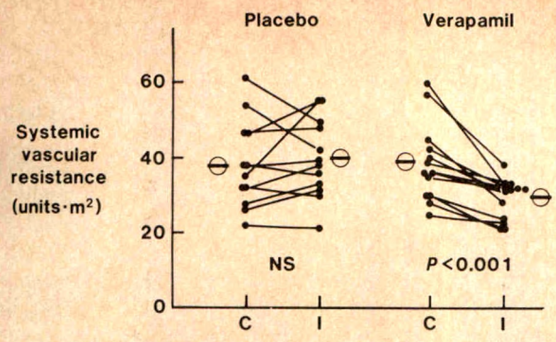

FIGURE 4. Systemic vascular resistance in placebo and verapamil treatment groups. C = control; I = intervention; NS = not significant.

Results

In all, 24 male patients and 1 female patient were entered into the study. Randomization resulted in allocation of 12 patients to the placebo group and 13 to the verapamil group. The 2 groups were similar in mean age and mean number of diseased vessels. The coronary arteriogram was normal in 1 patient in the placebo group and in 2 in the verapamil group. Mean baseline values were similar in the placebo and verapamil groups for heart rate, mean arterial pressure, cardiac index, left ventricular end-diastolic volume index, left ventricular end-systolic volume index, and left ventricular ejection fraction (Table I).

Control values and those obtained after the placebo or verapamil intervention are shown in Figures 1 through 5. Some patients showed considerable variation in heart rate, but the mean values were only slightly altered after either intervention (Fig. 1).

Although the mean arterial pressure was no different overall before and after infusion of placebo, the response to infusion of verapamil was consistent and highly significant (Fig. 2). The mean arterial pressure decreased in every subject; the mean decrease was 15%. The cardiac index increased in 9 of the 13 patients treated with verapamil and no change occurred in the placebo group (Fig. 3).

With the decrease in mean arterial pressure and the increase in cardiac index, the calculated systemic vascular resistance showed a highly significant reduction in the verapamil treatment group (Fig. 4). Postinfusion values were lower in every case. No significant change was noted in the placebo group.

TABLE II Effects of Verapamil on Left Ventricular Function: Response of Selected Variables

Variable	Placebo (12 Patients)		Verapamil (13 Patients)*	
	Before	After	Before	After
Left ventricular end-diastolic pressure (mm Hg)	17	19	16	19
Left ventricular end-systolic volume index (ml/m²)	37	34	39	41
Ejection fraction (%)	60	62	58	59

* Ventriculographic data available for only 9 patients.

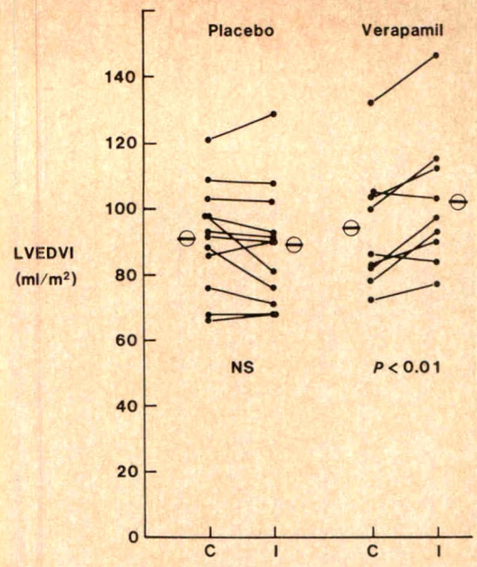

FIGURE 5. Left ventricular end-diastolic volume index (LVEDVI) in the 2 treatment groups. A significant increase was seen in the patients treated with verapamil ($p < 0.01$). C = control; I = intervention; NS = not significant.

A significant difference was found in the left ventricular end-diastolic volume index in patients after verapamil infusion but not in the placebo group. It increased in 7 of the 9 patients treated with verapamil in whom it could be calculated—from a mean of 94 to 102 ml/m² (Fig. 5). In 4 patients treated with verapamil, premature ventricular contractions rendered 1 of their ventriculograms unsuitable for analysis.

No significant response was detected after placebo or verapamil administration for left ventricular end-diastolic pressure, left ventricular end-systolic volume index, or ejection fraction (Table II). A small increase seen in left ventricular end-diastolic pressure after verapamil did not achieve significance, nor could any increase in left ventricular end-diastolic pressure be related to the initial level (range 7 to 26 mm Hg).

Peak rates of systolic thickening and diastolic thinning of the anterolateral wall were essentially unchanged after verapamil and placebo administration

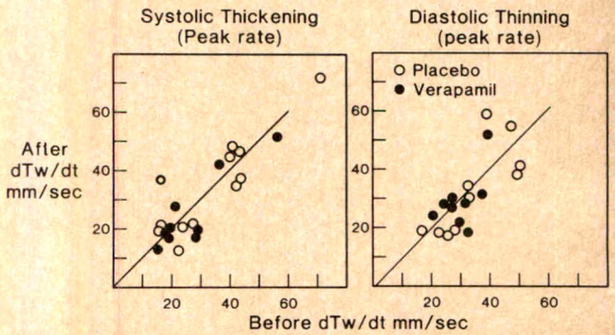

FIGURE 6. Maximal rate (dTw/dt) of systolic thickening and diastolic thinning for a single anterolateral left ventricular wall segment in placebo and verapamil treatment groups.

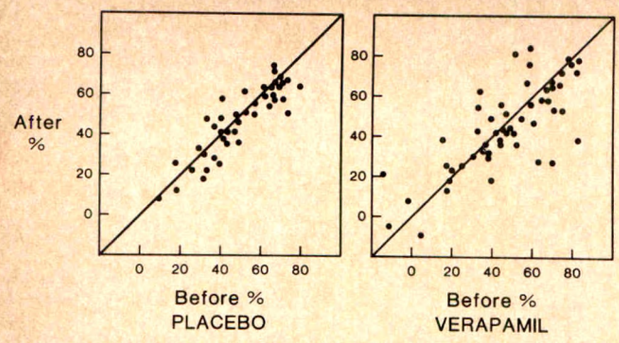

FIGURE 7. Hemiaxial shortening measured before and after the interventions with placebo and verapamil.

(Fig. 6). This was true not only for segments considered normal (dTw/dt ≥ 5.0 cm) but also for hypokinetic segments presumed ischemic, in which peak rates of systolic wall thickening were between 0 and 5.0 cm/s. In assessing such responses, it is necessary to evaluate the severity of the obstructive disease in the artery supplying the segment and the underlying state of the myocardium in that area.

In the placebo group, of 11 segments showing systolic hypokinesia, 6 were supplied by an artery with significant (that is, ≥50% stenosis) obstruction, and none of these had electrocardiographic evidence of anterior myocardial infarction. Of eight systolic hypokinetic segments in the verapamil group, 4 were supplied by an artery with significant obstruction, and 1 had electrocardiographic evidence of anterior myocardial infarction.

A total of 96 segments were suitable for analysis of hemiaxial shortening, both before and after infusion. Usually, 4 to 6 hemiaxes in each patient were suitable for this comparison. Poor endocardial opacification, especially in the left ventricular inflow region, led to the rejection of some segments from consideration. Although the verapamil group demonstrated greater variation in the values before and after intervention, there was no greater trend to either improvement or deterioration (Fig. 7).

Discussion

In patients with suspected coronary artery disease who do not have overt heart failure, verapamil lowers systemic vascular resistance, as evidenced by a decrease in arterial pressure and an increase in cardiac index. In this setting, the small but significant increase in the end-diastolic volume index observed seems most likely to represent a negative inotropic effect of verapamil, necessitating a larger end-diastolic volume to accomplish the increase in cardiac index associated with peripheral vasodilatation. This finding is consistent with the previously reported negative inotropic effects of verapamil in isolated cardiac muscle.[8,9] However, the possibility of a change in diastolic compliance of the ventricle cannot be excluded. The present findings differ from those of Ferlinz et al,[11] who reported an increase in left ventricular ejection fraction and circumferential fiber shortening, which they interpreted as improvement in left ventricular function with the use of verapamil. It should be noted that the quantitative indexes of left ventricular function reported by Ferlinz et al were determined from single-plane left ventriculograms by use of the area-length method, an approach with significant limitations in patients with coronary artery disease and regional left ventricular function abnormalities.[16]

The apparent negative inotropic effect observed in our study after a large intravenous dose of verapamil was unassociated with any changes that would be clinically evident. However, it provides support for caution in the use of the drug in patients with borderline compensation of left ventricular function, particularly in the presence of myocardial ischemia.

The studies reported here raise a number of questions relating to the mechanisms by which verapamil may provide relief of angina pectoris. Several possible mechanisms appear to exist, all of which could be operative to varying degrees, depending on the individual patient. The potent peripheral vasodilating effect of verapamil documented in the present study by a consistent decrease in arterial pressure, as well as by other evidence of both arterial and venous dilatation,[17] should produce a reduction in cardiac work and myocardial oxygen demands. These changes are not associated with reflex tachycardia, apparently because of the depressant effect of verapamil on pacemaker and conduction tissue[18]; thus, an additional stimulus for increased oxygen demand is avoided.

Another possible mechanism for relief of angina with verapamil is an increase in blood flow to the ischemic area through collateral channels and direct vasodilatation of the atherosclerotic segment of the coronary artery. Verapamil has been demonstrated to have a potent vasodilating effect in extramural coronary arteries.[19] That vasodilating agents may have a major effect on improving flow, even through so-called fixed coronary arteries, receives strong support from the recent work of Brown et al[20] on the effect of nitroglycerin on such lesions, in which a computer-based quantitative method was used to determine changes in the degree of obstruction. Although several studies have shown no change in the rate-pressure product for angina after verapamil treatment,[21,22] data are reported on patients with stable angina which indicate that another calcium-channel blocker, lidoflazine, improves regional perfusion of ischemic myocardium during exercise.[22]

The lack of improvement in regional function of hypokinetic areas after administration of verapamil in the present study raises the question of local reduction of myocardial oxygen demands. There are data to support the use of rates of wall thickening and thinning as indexes of myocardial ischemia in animal models[23] (St. John Sutton M, Ritman EL: unpublished data). Thus, if an intervention relieves ischemia, one would expect an improvement in such areas if the muscle is still viable and the intervention produces no inotropic effect. This is the case in the studies reported by Dumesnil et al[14] and Chesebro et al,[15] in which the intervention is with nitroglycerin. However, with verapamil, an agent known to have negative inotropic effects, a different response

occurs. In spite of peripheral and central effects, which result in decreased oxygen demand and perhaps increased regional blood flow, no regional improvement in function occurs. Previous studies have suggested that ischemic areas of myocardium may, in fact, be most susceptible to the negative inotropic effects of verapamil, in contrast to propranolol, which affects both normal and ischemic tissue by depressing function.[24] Such negative inotropic effects in a local area of myocardial ischemia might contribute to relief of angina pectoris, not only on the basis of decreased myocardial oxygen demands but also through facilitation of local flow, as demonstrated by Marzilli et al.[25]

The observations in our study on regional wall dynamics differ from those reported by Ferlinz et al,[11] who used the measurement of hemiaxes as an index of regional function. That investigation reported frequent improvement with verapamil therapy, but no control group was included. In our study, the use of a placebo-controlled design helps resolve this difference, in that changes similar to those in the verapamil group could be observed in the placebo group as well. This reflects the limitations of the hemiaxial method in assessing regional function, because the identification of axes is highly subjective and is influenced by cardiac motion.

Acknowledgment: We thank the Knoll Pharmaceutical Company for financial support and the supply of verapamil used in this study.

Hemodynamic and Electrocardiographic Effects in Man Of a New Nonionic Contrast Agent (Iohexol): Advantages Over Standard Ionic Agents

G. B. JOHN MANCINI, MD, FRCP, J. NEUKAM BLOOMQUIST, MSN, VALMIK BHARGAVA, PhD, JOSEPH B. STEIN, MD, WILBUR LEW, MD, ROBERT A. SLUTSKY, MD, RALPH SHABETAI, MD, and CHARLES B. HIGGINS, MD

Iohexol is a new, nonionic contrast material that has been shown in animal studies to hold great promise as an agent for coronary arteriography and ventriculography with fewer adverse hemodynamic effects than standard ionic media. At present, it has not been studied systematically in man. Fifty patients referred for elective cardiac catheterization were randomized to receive either iohexol or meglumine sodium diatrizoate (Renografin®-76). Both operator and patient were blinded as to which agent was being used. Hemodynamic variables measured were pulmonary artery wedge pressure and systemic blood pressure. In addition, the following electrocardiographic indexes were evaluated: S-T segment shifts, changes in Q-T interval, changes in T-wave amplitude, and changes in heart rate. These variables were measured after left ventriculography and after both left and right coronary arteriography. Both iohexol and sodium meglumine diatrizoate produced small transient elevations in pulmonary artery wedge pressure. Systemic hypotension occurred with both agents but was more profound and longer-lasting with sodium meglumine diatrizoate. Iohexol injection resulted in no electrocardiographic changes, whereas sodium meglumine diatrizoate produced marked Q-T prolongation, as well as changes in T-wave amplitude and heart rate. Iohexol was well tolerated by the patients, and radiographic opacification was good to excellent in all cases. Thus, iohexol produces fewer deleterious hemodynamic and electrocardiographic changes than sodium meglumine diatrizoate when studied in a typical adult population requiring diagnostic cardiac catheterization. This favorable preliminary experience in man has potential widespread importance because of the large number of patients undergoing angiographic procedures.

The deleterious effects of ionic contrast material on myocardial function during coronary arteriography and contrast ventriculography have long been appreciated.[1–8] These effects include a reduction in left ventricular peak systolic pressure and both global and regional myocardial function, as well as adverse electrophysiologic changes. These perturbations occur more frequently in the presence of coronary stenoses.[8,9] Important etiologic factors in the generation of these phenomena include excessive amounts of single-valence cations such as sodium and meglumine in the media, contrast-induced hypocalcemia and hypokalemia, and the osmolality of these solutions.[1,2,6,10–18] Sodium meglumine diatrizoate (Renografin®-76) has frequently been shown to produce these adverse cardiovascular effects, and at present is the most commonly used angiographic contrast medium. Efforts to develop nonionic contrast agents devoid of these toxic properties have been pursued. Such an agent would be expected to be safer for general patient use and would interfere less with the ability of the clinical cardiologist to interpret physiologic data from angiographic data. Metrizamide (Amipaque®) was the first generally available nonionic contrast agent to demonstrate some of these advantages; however, its expense and hydrolytic instability make it less than ideal for routine clinical use.

Iohexol is a new, nonionic contrast material which has a long shelf life in solution and is hydrolytically stable. Although extensive research in laboratory animals has shown that iohexol causes less severe hemodynamic[9] and electrocardiographic alterations[17] than standard ionic contrast media, a systematic comparison of iohexol and sodium meglumine diatrizoate during coronary

arteriography and left ventriculography in man has not been undertaken. This study was designed to investigate the hemodynamic and electrocardiographic differences between iohexol and sodium meglumine diatrizoate during elective cardiac catheterization in adult patients.

Methods

All patients referred for elective cardiac catheterization were eligible for this study except (1) patients with a serum creatinine level >3.0 mg/100 ml; (2) those with a known sensitivity to iodine; (3) pregnant or lactating women; and (4) patients who had received contrast media within 48 hours of the study. The patients and the angiographer were blinded as to which contrast agent was being utilized. The study was terminated when 50 patients (25 in each group) had been randomized to receive either sodium meglumine diatrizoate or iohexol. Pertinent clinical features of these 2 groups are shown in Table I. The 2 groups were composed of patients with similar clinical and angiographic findings (no significant differences with chi-square analysis).

Patients were studied by either the Sones or Judkins techniques after premedication with oral diazepam, 5 to 10 mg, and diphenhydramine, 25 to 50 mg. A Potts-Cournand needle was inserted into the left brachial artery for continuous monitoring of systemic pressure. A #7 French flotation catheter was advanced into the pulmonary artery wedge position.

Variables were analyzed for 2 minutes after left ventriculography and for 1 minute after each of the first left and right coronary artery injections: The variables were measured during a preinjection control period, at 5-second intervals for 20 seconds after dye injection, and at 10-second intervals thereafter. Left ventricular injection was performed during held inspiration whereas the first selective injection into each coronary artery was performed during quiet respiration. An interval of approximately 15 minutes elapsed between left ventriculography and coronary arteriography. The amount of dye used for each injection was recorded and is shown in Table I.

The hemodynamic variables of interest were the systemic systolic arterial pressure and the pulmonary wedge pressure. The S-T segment shifts, Q-T interval, T-wave amplitude, and heart rate were also measured from limb lead II of the electrocardiogram. All recordings were made at a strip chart speed of 100 mm/s.

The protocol was approved by the Human Subjects Investigation Committee of the University of California, San Diego; all patients gave informed consent.

Statistics: All data were analyzed by repeated analysis of variance to test for (1) changes induced by each agent over time, (2) differences between the effects of each agent at specific points in time, and (3) differences in the overall time course of changes between the contrast media. Differences were considered significant if p was <0.05. Tabular data are presented as mean ±1 standard deviation whereas the data in graphs represent mean ±1 standard error of the mean.

Results

The preinjection control values are provided in Table II. No statistical difference at control was noted between the groups except for the systemic systolic pressure before left ventriculography, which was significantly higher for the iohexol group ($p < 0.05$). Data are therefore presented in raw form in order to not exaggerate differences between the agents when percent changes are analyzed.

Hemodynamic effects: Figure 1 summarizes the results of these measurements for both groups. The sequence of changes in pulmonary wedge pressure was the same for the sodium meglumine diatrizoate group

TABLE II Control Values

	Left Coronary Injection		Right Coronary Injection		Left Ventriculography	
	R76	Iohexol	R76	Iohexol	R76	Iohexol
Pulmonary wedge pressure (mm Hg)	8 ± 10	10 ± 6	8 ± 4	10 ± 5	9 ± 4	11 ± 8
Systemic systolic pressure (mm Hg)	135 ± 20	148 ± 28	132 ± 20	144 ± 26	133 ± 19	152 ± 25*
S-T segment (mV)	−0.02 ± 0.10	−0.06 ± 0.08	−0.02 ± 0.11	−0.09 ± 0.21	−0.03 ± 0.10	−0.05 ± 0.08
Q-T interval (ms)	434 ± 52	420 ± 57	430 ± 59	428 ± 54	431 ± 51	424 ± 51

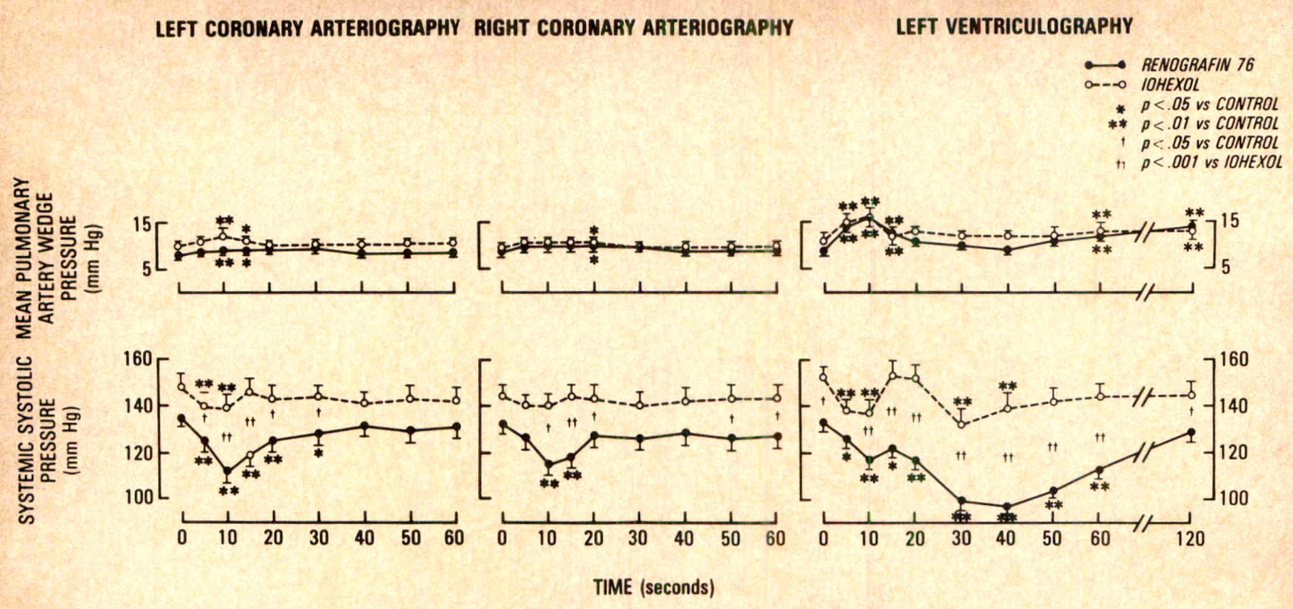

FIGURE 1. Hemodynamic changes induced by contrast agents.

and the iohexol group. While both agents induced small but statistically significant elevations in the mean pulmonary artery wedge pressure, there were no differences in the degree of this change between the 2 forms of media. In contrast, the time course of changes in systolic pressure induced by iohexol was significantly different from those induced by sodium meglumine diatrizoate after left and right coronary arteriography ($p < 0.05$) and after left ventriculography ($p < 0.001$), and in all 3 instances, the curves were flatter for iohexol and varied from control for shorter periods than the sodium meglumine diatrizoate group. Iohexol induced no blood pressure change after right coronary arteriography. After left coronary arteriography and left ventriculography, both agents produced significant decreases in pressure, but in both cases the decreases were smaller and less sustained after iohexol than after sodium meglumine diatrizoate. Furthermore, although the control blood pressure before left ventriculography was higher in the iohexol group, the trend analysis confirmed a significantly greater and longer lasting blood pressure decrease with sodium meglumine diatrizoate than with iohexol ($p < 0.001$).

Electrocardiographic effects: Figure 2 summarizes the results of the electrocardiographic measurements for both groups.

The S-T segment did not change significantly over time for either agent. Iohexol induced no changes in Q-T interval, T-wave amplitude, or heart rate. In marked contrast, sodium meglumine diatrizoate produced a substantial increase in the Q-T interval after left and right coronary arteriography and an increase in T-wave amplitude after left coronary arteriography. Furthermore, the heart rate was significantly depressed after coronary anteriography, and it increased significantly after left ventriculography performed with sodium meglumine diatrizoate.

Discussion

Iohexol is a new, nonionic, water-soluble contrast medium that has been shown to have great promise as a preferred agent for coronary arteriography and ventriculography in animal experimentation and in preliminary human studies. It does not dissociate in aqueous solution, contains negligible amounts of sodium, and the osmolality is approximately half that of ionic contrast agents (Table III). These properties provide a theoretical basis for the fewer hemodynamic and electrophysiologic effects of this agent as compared with ionic media. Furthermore, unlike metrizamide, a lyophilized nonionic substance which must be reconstituted before use, iohexol is premixed, stable in solution (even with autoclaving), and maintains its pH within a critical range for diagnostic angiography.

Animal studies have demonstrated fewer biochemical, electrocardiographic, and hemodynamic derangements induced by iohexol than by ionic contrast media.[9,19–28] Gerber et al[9] demonstrated significantly greater changes in left ventricular systolic pressure, first derivative of left ventricular pressure (dP/dt), dP/dt at 50 mm Hg developed pressure, end-systolic myocardial segment length (L), and first derivative of myocardial segment length (dL/dt) during sodium meglumine diatrizoate injection than with iohexol. They also noted that these effects were more marked in the ischemic state. Unlike sodium meglumine diatrizoate, iohexol does not cause any reductions in coronary sinus calcium or potassium levels and this may partially explain its fewer cardiodepressant effects.[9]

Higgins et al[28] demonstrated drastic biphasic changes in left ventricular pressure and dP/dt, and moderate changes in end-systolic dimension in response to the intravenous injection of sodium meglumine diatrizoate. In the same study, iohexol caused little or no change in

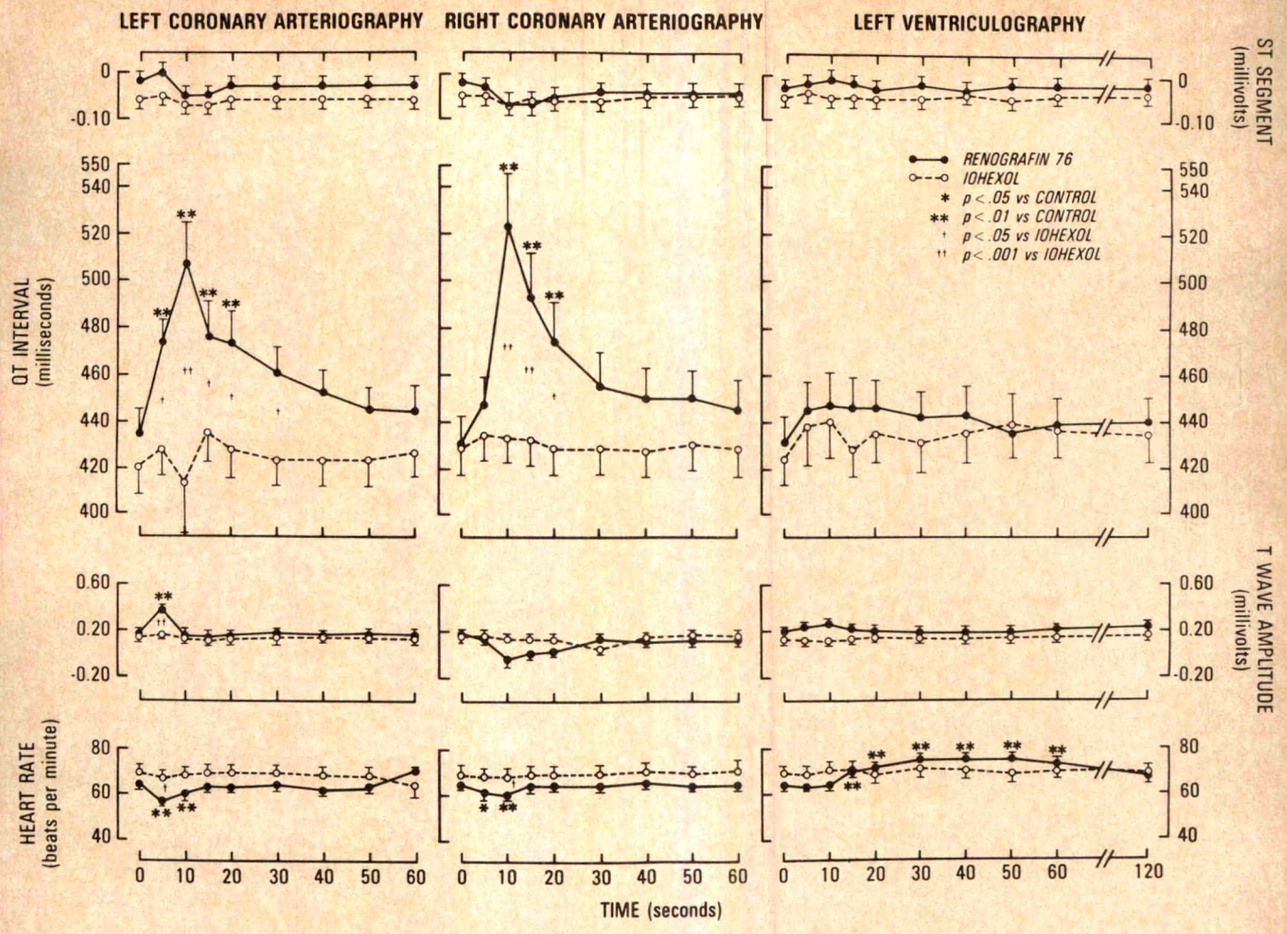

FIGURE 2. Electrocardiographic changes induced by contrast agents.

left ventricular pressure and dimensions. In addition, sodium meglumine diatrizoate caused marked arterial hypotension and large increases in coronary blood flow, while iohexol caused no significant changes in arterial pressure and coronary blood flow, and a mild increase in femoral blood flow. Based on these results, it was concluded that iohexol is preferable to standard ionic agents for deriving basic physiologic information from angiographic studies, including computed tomography and digital angiography.

Preliminary use of iohexol in humans has been reported by Aakhus et al.[29] This group demonstrated no significant heart rate, blood pressure, or electrocardiographic changes in 20 healthy volunteers who received 125 to 500 mgI/kg body weight of iohexol given intravenously. The injection was generally well tolerated, and a transient heat sensation was felt in only 6 of 10 patients who received the highest doses. This group also documented nearly complete renal excretion of unchanged iohexol within 24 hours of injection.

The present study reports our initial clinical experience with the use of iohexol for routine diagnostic cardiac catheterization. We found that iohexol produced a lesser degree of systemic hypotension after coronary angiography and left ventriculography. Furthermore, it induced no deleterious electrocardiographic changes as reflected by S-T segment shift, Q-T prolongation, changes in T-wave amplitude, or heart rate. The degree

TABLE III Physical Characteristics of Contrast Materials

	Iodine (mg/ml)	Osmolality (mOsmol/kg)	Viscosity Centipoise 20°	Viscosity Centipoise 37°C	Sodium (mEq/liter)	Calcium (mEq/liter)	Sodium Citrate mg/ml)	Disodium Edetate (mg/ml)
Sodium meglumine diatrizoate	370	1680	13.8	8.4	190	. . .	3.2	0.4

* Calcium disodium edetate.

of opacification in all studies was also good to excellent and the agent was well tolerated by the patients.

We therefore conclude that iohexol has the potential benefit over ionic contrast material of producing fewer deleterious hemodynamic and electrocardiographic changes in patients undergoing diagnostic cardiac catheterization. These properties and the availability of the agent in a stable, premixed form with a long shelf life make it a practical and preferred contrast medium for routine clinical use. Such advantages are important for safer angiography, particularly in patients with coronary stenoses,[8,9] patients who are already hemodynamically unstable, and perhaps also for patients who suffer from arrhythmias. In addition, investigational studies using angiographic techniques should probably be carried out with an agent such as iohexol to avoid many of the physiologic derangements induced by standard ionic media.

Increased Left Ventricular Function as an Adaptive Response in Vibration Disease

TSUNETAKA MATOBA, MD, MORIO ITAYA, MD, KOJI TOYOMASU, MD, TAKEYOSHI TSUIKI, MD, HIRONORI TOSHIMA, MD, and HIROSHI KUWAHARA, MD

Vibration disease results from the long-term use of vibrating tools. Vibration, noise, and cold are stressors that impair the human body, inducing vibration disease. From echocardiographic methods, the left ventricular ejection fraction in vibration disease was 79 ± 4%, a significantly higher value than that in control subjects (75 ± 6%) ($p < 0.01$). The increase in ejection fraction appeared to be due mainly to an increase in left ventricular end-diastolic dimension. The value of the ejection fraction was proportional to the activity of the autonomic nerves. The stroke volume index in patients with vibration disease was also significantly larger than that in the control subjects ($p < 0.001$). Electrocardiograms revealed a significantly lower heart rate at rest and an increase in the ratio of T waves to R waves in precordial lead V_6. These data suggest that the cardiovascular system in patients with vibration disease provides an adaptive response to the stressors.

Since 1911, long-term use of vibrating tools such as chain saws, pneumatic hammers, or electric hammers has been known to result in injury to peripheral blood vessels and nerves, giving rise to Raynaud's phenomenon in the fingers. This occupational disease has been called "white finger" or "vibration-induced white finger." [1] Recently, this condition has been recognized as a systemic disease. Long-term vibration impairs not only peripheral circulatory and nervous function, but also central nervous function.[2] The patients are afflicted with Raynaud's phenomenon and numbness of the fingers, insomnia, headache, palmar hyperhydrosis, fatiguability, tinnitus, and impotence.

The vibration and noise generated by vibration tools as well as the cold environment impair the human body.[2,3] Long-term exposure to these stressors could induce defense mechanisms in the human body. In particular, the sympathetic nervous system may become hyperreactive, and the adrenohypophyseal system may be excited.[4] Under these conditions, the cardiovascular system could adapt to the stressors. The patient would manifest signs and symptoms such as cardiomegaly, sinus bradycardia, and low blood pressure.[3] This study evaluates by echocardiography and electrocardiography the cardiovascular function of patients with vibration disease.

Methods

The study group consisted of 35 men with vibration disease and a control group of 35 healthy men. All the subjects underwent physical and laboratory examination to exclude the possibility of cardiovascular or hormonal disease. All were physical laborers (farmers, firemen, railroadmen, carpenters, and industrial workers). The subjects of both groups were matched by age which ranged from 36 to 64 years. The average age in patients with vibration disease was 49 ± 7 years (mean ± standard deviation [SD]) and in the control group 48 ± 7 years. Chain saws and jack hammers were used by 20 and 15 men, respectively, for 16 ± 5 years (mean ± SD). The mean period between the last use of a vibrating tool and the examination was 3 ± 1.4 years (mean ± SD).

A standard M-mode echocardiogram was recorded in all subjects by 1 technician. The left ventricular ejection fraction was calculated from measurements of left ventricular end-diastolic and end-systolic dimensions in the echocardiogram, using the following formula: $(LVDd^3 - LVDs^3)/LVDd^3$, where LVDd = left ventricular end-diastolic dimension and LVDs = left ventricular end-systolic dimension.

Electrocardiograms (12 leads) were recorded in the supine position at a paper speed of 25 mm/min. The following variables were studied: heart rate calculated from the mean of 3 beats; the algebraic sum of Q, R, and S deflections in standard leads (R in lead I + S in lead III) and in precordial leads (S in lead V_1 + R in lead V_5); and the ratio of the amplitudes of T waves to those of R waves in leads I, V_5, and V_6. The activity
